7. Plasma Distribution and Spacecraft Charging Modeling Near Jupiter

Raymond Goldstein and Neil Divine
Jet Propulsion Laboratory
Pasadena, California

Abstract

To assess the role of spacecraft charging near Jupiter, the plasma distribution in Jupiter's magnetosphere has been modeled using data from the plasma analyzer experiments on Pioneer 10 (published results) and on Pioneer 11 (preliminary results). In the model, electron temperatures are \( kT \sim 4 \text{ eV} \) throughout, whereas proton temperatures range over \( 100 \leq kT \leq 400 \text{ eV} \). The model fluxes and concentrations vary over three orders of magnitude among several co-rotating regions, including, in order of increasing distance from Jupiter, a plasma void, plasma sphere, sporadic zones, ring current, current sheet, high latitude plasma and magnetosheath. Intermediate and high energy electrons and protons (to 100 MeV) are modeled as well. The models supply the information for calculating particle fluxes to a spacecraft in the Jovian environment. The particle balance equations (including effects of secondary and photoemission) then determine the spacecraft potential. Negative potentials the order of \( 10^4 \text{ volts} \) are calculated in the near region (magnetic shell parameter \( \leq 6.5 \text{ Jovian radii} \)). In the outer region, severe differential charging (\( \sim 10^4 \text{ volts} \)) can occur for shadowed, electrically isolated portions of the spacecraft.

This paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under Contract No. NAS7-100, sponsored by the National Aeronautics and Space Administration.
1. INTRODUCTION

Several facts suggest that spacecraft operating in Jupiter's magnetosphere can charge to significant potentials. These include the existence of a highly structured magnetosphere, with novel features compared to the earth's, and known to contain both stable and dynamic populations of thermal and energetic (MeV) electrons and ions. Experience with spacecraft in earth environment, especially at synchronous altitudes, shows that spacecraft charging occurs in such environments, and some anomalies in the operation of the Pioneer 10 and 11 spacecraft near Jupiter have been attributed to such charging. The survival and satisfactory operation of a spacecraft orbiting in the Jovian environment is thus of concern, because of the long period of time spend in the severe environment. To assess this problem, environmental models developed from Pioneer data are described below and are applied to preliminary computations of likely spacecraft equilibrium potentials in several magnetosphere regions, in both sunlight and shadow.

2. PLASMA MODEL DEVELOPMENT

The major features of Jupiter's thermal plasma distributions are derived from Frank et al., who present a thorough discussion of the proton component data from the plasma analyzer experiment on Pioneer 10. These data range over values of L (magnetic shell parameter, in Jovian radii $R_J$) between 2.85 and 25 (within the centrifugally dominated region) and are summarized in their Figure 8. Comparable results from Pioneer 11 are not yet complete but the major additional results are: a plasma void for $L \leq 1.8$ to 2.0 (within the gravitationally dominated region), and plasma properties nearly independent of latitude for $L \leq 12$. For high latitudes at $L > 12$, the density is assumed about an order of magnitude smaller than in the current sheet.

For the electron component more limited results, from Pioneer 10, are discussed by Intriligator and Wolfe, the main conclusion being an electron peak in energy near 4 ev throughout the magnetosphere. Assuming charge neutrality (that is, electron concentrations equal to proton ones) an electron model can be inferred from the above proton distribution.

Ancillary information has been used in the models as follows, in order of increasing distance from Jupiter. Fjeldbo et al., who reports results of Pioneer 10 radio occultations, provide information which has been used for a very crude specification of the ionosphere; for details of this multilayered environment in Jupiter's upper atmosphere the original reference should be consulted. Near the Galilean satellite Io, the configuration of the atomic hydrogen torus suggests a
local proton concentration which ionizes H by charge exchange$^{4, 5, 6}$ and the atomic sodium distribution suggests the importance of ionization by local electrons.$^7$

These results have been used to confirm or modify the description of the plasma sphere. Magnetic field data from Pioneer 10 confirm the reality of the ring current (the source of external field terms for magnetic field modeling),$^8$ and the proton concentration in the current sheet.$^9$ Elsewhere various indirect observations and theoretical considerations are generally consistent with the foregoing interferences; they include discussions of Faraday rotation for HF bursts,$^{10}$ waveparticle interactions (diffusion, whistlers, etc.),$^{11, 12, 13, 14}$ and numerous, primarily qualitative, analyses.$^{15, 16, 17, 18, 19, 20}$ A description of the magnetosheath plasma is taken from considerations of Figure 5 of Wolfe et al.$^{21}$

The present preliminary plasma model should be improved to include aspects of the extended distribution of neutral sodium atoms$^7$ which is possibly in equilibrium with a sodium ion population. In addition, there are observations of neutral hydrogen,$^6$ suggesting protons, and of an ionized sulfur nebula.$^{22}$ Other considerations for modification of the model include the character of the 4 eV electron peak seen at large $L$. This is not clearly thermal in origin and could have been the result of differential charging on Pioneer 10.$^{23}$ The low energy data from the San Diego scintillators on Pioneer 11$^{24}$ should also be included.

3. PLASMA MODEL SPECIFICATION

The plasma distribution derived from the above considerations is specified in Table 1, and the several regions and their boundaries are illustrated in Figure 1.

Values and uncertainties for boundaries and concentrations (equal for electrons and protons) have been estimated. The thermal energy values are quoted without uncertainty because the uncertainties in the distributions which result from the concentration column are already large. In the co-rotating frame [see note (2), Table 1], the thermal distributions are isotropic and may be derived from the entries in Table 1 using the following formulae:

$$J_o = 2N_o \left( \frac{2kT}{\pi m} \right)^{1/2}$$

$$= (1.56 \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}) N_o (kT)^{1/2} \text{ for protons}$$

or

$$= (6.69 \times 10^7 \text{ cm}^{-2} \text{ s}^{-1}) N_o (kT)^{1/2} \text{ for electrons}.$$

Notes:
1. A location is outside the current sheet if both conditions are met: $L > (12 \pm 1) R_J$ and $|Z| > (1 \pm 0.5) R_J$.
2. If the speed $v$ relative to the co-rotating plasma exceeds the proton thermal speed, the appropriate entries must be replaced by $mv^2 / 2$ and $N_p$ for a stationary observer $v = (1 \times 10^6 \text{ cm/s}) (R/R_J)$ and $E = mv^2 / 2 = (0.83 \text{ eV}) (R/R_J)$ dominate for $R > 22 R_J$.
3. These boundary locations vary strongly with direction from Jupiter (cf. Eq. 63 for $R_{M1}$) and with time in response to changes in the external solar wind.
4. In the magnetosheath, the variable bulk plasma flow ($v = 300 \text{ km/s}$) dominates the proton thermal speed, so the corresponding flux entry is $N_p$. 

Figure 1. Schematic of Plasma Regions at Jupiter for One Quadrant of a Magnetic Meridional Plane. Drawing is not to scale, although three distances (in $R_J$) from Jupiter are indicated along the magnetic equator.

\[
J = J_0 (1 + E/kT) \exp \left(-E/kT\right) + J_2 + j_2 (E_2 - E) \quad (2)
\]

\[
j = J_0 E (kT)^{-2} \exp \left(-E/kT\right) + j_2 \quad (3)
\]

In these expressions, values of $N_o$, $J_o$, and $kT$ are to be taken from Table 1; in that table, $Z$ represents the vertical distance from the magnetic equatorial plane, and the notes are important. Equations (1) through (3) apply for all thermal and intermediate energies $0 \leq E \leq E_2$ and specify fluxes $J$ and $j$ which are continuous with those in: the radiation belt models (see below) when $J_2$ and $j_2$ are evaluated at energy $E_2$, where $E_2 = 40,000$ eV for electrons and $E_2 = 610,000$ eV for protons. Care should be taken that energy unit conversions (between MeV and eV) are included when $J$ and $j$ are evaluated in $\text{cm}^{-2} \text{s}^{-1}$ and $\text{cm}^{-2} \text{s}^{-1} \text{eV}^{-1}$ respectively.

For completeness, in Table 1 reference is made to NASA SP-8118 for a description of parameters in the solar wind.
I. ENERGETIC PARTICLE MODEL

For energies exceeding \( E_2 \) (see above), there exists a large body of data from four energetic charged particle experiments on each of the Pioneer 10 and 11 spacecraft. Because the literature sources and the model specification for this environment are so detailed, they will not be described here. The former are exemplified by several articles in *Journal of Geophysical Research*, Vol. 79, No. 25 (1974, Sept. 1) and in *Science*, Vol. 188, No. 4187 (1975, May 2). The model has been developed for the Jupiter-Orbiter-Probe Study, and has been published for limited distribution.\(^{26}\) As an example, inner magnetosphere electron flux profiles are shown in Figure 2. The complete radiation belt model includes both integral and differential fluxes as functions of position \( L \) and \( \lambda \) (magnetic latitude) and particle energy, for both electrons and protons.

5. SPACECRAFT CHARGING CALCULATION

The net current to the spacecraft $I_{\text{net}}$ is given by

$$I_{\text{net}} = I_p - I_e + I_s + I_{\text{PE}}$$  \hspace{1cm} (4)

where $I_p$ is the total proton current intercepted by the spacecraft, $I_e$ is the incident electron current, $I_s$ is the total secondary electron emission from the spacecraft (including backscattered electrons), and $I_{\text{PE}}$ is the photoelectron emission current from the spacecraft. Each term is a function of the spacecraft potential $V_{s/c}$ because of the energy dependence of each term. At steady state the net current must be zero, establishing the condition for determining $V_{s/c}$. If Equation (4) is divided by the appropriate area, this condition can be expressed in terms of particle fluxes. It is assumed that essentially all of the spacecraft is covered with electrically conductive material, and that on the average, only 25 percent of the surface is exposed to sunlight. Then the condition for zero net current becomes

$$J_p(V_{s/c}) - J_e(V_{s/c}) + J_s(V_{s/c}) + J_{\text{PE}}(V_{s/c}) = 0$$  \hspace{1cm} (5)

The $J$'s represent the particle fluxes of the corresponding terms of Eq. (4); and the dependence on $V_{s/c}$ is explicitly shown for emphasis. To normalize the photoelectric term properly, a factor 0.25 is implicitly included in $J_{\text{PE}}$.

Equation (5) was used to calculate $V_{s/c}$ at various locations in the Jovian magnetosphere using values of $J_p$ and $J_e$ provided by the model described in the previous sections. The results of Sternglass for aluminum, as reported by Whipple, were used to calculate $J_s$. Whipple's value of photoelectron yield for aluminum at 1 AU ($3 \times 10^{-9}$ A cm$^{-2}$) reduced for 5.2 AU, was used to determine $J_{\text{PE}}$. Although most spacecraft are not likely to be covered with aluminum, the yields were taken to be typical of conductive materials.

The calculations were performed by assuming a $V_{s/c}$ and then iterating until a self-consistent value could be obtained. Usually a rapid convergence of the calculation was obtained with very few iterations. This is largely due to the dependence of the secondary emission yield on incident proton energy. Below about $10^3$ eV the yield is much less than unity, but above $10^3$ eV the yield rises very rapidly with energy exceeding unity at about $2 \times 10^3$ eV. This rapid increase in yield with energy produces a high sensitivity of the calculation to $V_{s/c}$ since all low energy protons are accelerated by a negative spacecraft potential. The high secondary yield thus tends to limit negative spacecraft potentials to a few keV in regions of the magnetosphere where photoemission is unimportant.
6. RESULTS AND DISCUSSION

The contribution of each term of Eq. (5) at the steady state spacecraft potential for several locations in the Jovian equatorial plane is shown in Figure 3. The calculated spacecraft potentials are also given. The lower part shows the incident electron current density. In the upper part of the figure, the proton as well as secondary and photoemission contributions are shown. Note that for \( L \leq 6.5 \text{ R}_J \), photoemission is not every important. For higher \( L \), however, photoemission begins to dominate and the spacecraft charges to a slight positive potential. In those cases the actual secondary and photoemission contributions depend on details of their energy distributions, and for simplicity were not calculated in detail. Their sum is thus shown in Figure 3 for \( L \geq 9.5 \text{ R}_J \).

The incident electron current density corresponding to the \( V_{\text{S/C}} \) calculated at steady state is indicated by the light horizontal line shown in the electron contributions separating two differently shaded regions. The full column represents the total \( J_{e}(0) \) that would occur if the potential were zero, and hence the doubly cross-hatched region corresponds to that portion of the electron spectrum repelled by the spacecraft to produce the current balance.

Figure 3. Distribution of Particle Fluxes to and From Spacecraft in Jovian Equatorial Plane
The heavy horizontal line appearing in each column shows the relative contribution to the total incident flux due to low energy plasma particles and high energy particles. In each case the plasma contribution is the portion closest to the center of the figure.

Calculations were also carried out neglecting the photoemission term, that is, for a spacecraft in eclipse. In the inner region, where photoemission is unimportant (cf. Figure 3), potentials for the dark case are not very different from the sunlit case. However, in the outer regions where photoemission is important, relatively high potentials are calculated for a spacecraft in darkness. The potentials for both the sunlit as well as eclipse cases are summarized in Table 2. Also shown there are the potentials calculated for one point in the high latitude region (L = 16.0 R_J,  \( \lambda = 45^\circ \)). In the outer regions total eclipse of the spacecraft is unlikely, but the eclipse potentials indicate the level to which electrically isolated portions in darkness are likely to charge.

Some calculations were also performed to determine the sensitivity of the results to the fraction of the spacecraft assumed to be in sunlight. In the inner region this is not too important, but in the outer region a 10 percent sunlit spacecraft would have a negative \( 10^{-2} - 10^0 \) potential.

7. SUMMARY AND CONCLUSIONS

A model of the Jovian charged particle environment has been constructed from results of Pioneer 10 and 11 measurements. This model was used to calculate the potential to which a spacecraft would charge in the Jovian environment. In the inner region ($L \leq 6.5 \, R_J$), the potentials calculated ($\sim 10^3$ volts negative) indicate severe disturbances to fields and particles measurements from the spacecraft. "Clean" measurements would therefore require active control of the spacecraft potential. In the outer regions, electrically isolated portions of the spacecraft are likely to charge differentially $\sim 10^3-10^4$ volts with respect to sunlit portions. High differential charging seriously distorts fields and particles measurements, and represents sources for arcing severe enough to damage the spacecraft or cause malfunction.
