FOREWORD

This final report is submitted to Aerospace Environment Division, Space Sciences Laboratory, Science and Engineering Directorate, NASA-Marshall Space Flight Center, Alabama, in partial fulfillment of requirements under Contract No. NAS8-31806.

Science Applications, Inc., is indebted to Dr. Briscoe Stephens, Atmospheric Diffusion/Environmental Assessment Task Team, Aerospace Environment Division, for the technical guidance and useful suggestions in planning the revision to the NASA/MSFC Multilayer Diffusion Models and in the development of the objective meteorological parameter selection concepts. The suggestions and the assistance of the following are gratefully acknowledged: the H. E. Cramer Company - diffusion modeling; the IIT Research Institute - scavenging and washout data; Dr. Ronald Dawbarn of ARO, Inc. - Al₂O₃ experiments; NASA Langley Research Center - measurements and laboratory chemistry; McDonnell Douglas Corporation - Delta Thor parameters; Chemical Systems Division of United Technologies Corporation - Titan III booster parameters; U.S. Air Force Weather Service and their range contractor, Pan American World Airways, Inc. - meteorological data collected at Kennedy Space Center. The work under this contract is under the direction of Arnold I. Goldford, Science Applications, Inc.

1. INTRODUCTION

This final report discusses efforts made on a study over the last nine months which had as its primary objective the development of techniques to determine the environmental effects from the Space Shuttle SRB exhaust effluents. This determination required the blending together of a team which had diverse skills and capabilities. The study required personnel with experience and knowledge in propulsion chemistry, meteorology, computer technology, and fluid dynamics. The study utilized four different computing systems; the NASA REEDA, the NASA UNIVAC 1108, the NASA IBM 360, and the SAI IBM 370. Knowledge of their operating systems and details of similarities and differences between the machines' data storage, instructions, and peripheral equipment operations was required during the study. Intimate knowledge of meteorological data reduction methods was a necessity. The start of the development of the new cloud rise model required expertise in fluid dynamics. To obtain the source terms for the cloud rise calculations required a state-of-the-art analysis of the SRB and its exhaust effluents.

This study has developed many new and needed tools for the determination of the environmental effects from the Space Shuttle SRB exhaust effluents. A preliminary climatological assessment has been performed which will be used to guide the future full scale climatological assessment. The exhaust effluent chemistry study has been performed and the exhaust species have been determined neglecting several possibly important effects. A reasonable exhaust particle size distribution has been constructed which can be used for the deposition model. The effects of scavenging and absorption have not been included in the preliminary climatological assessment. The basic conclusion that can be drawn regarding the entire study is that the team has now done their homework, understands the complete problem more
fully, has developed the required algorithms, learned the required technology, and is now able to perform a meaningful climatological assessment with the operational REED Description which can yield the required answers about the environmental effects from the Space Shuttle SRB exhaust effluents. These algorithms have not been interfaced into the REED Description.

Section 3 on the exhaust chemistry and Section 6 on the numerical cloud rise model are efforts funded under NASA Contract NAS8-31851. The partial results have been included in this report so that a reader can get a clear picture of the overall effort. It should be noted that the basic studies have been conducted with a Titan type vehicle having all solid propellant motors and not the Space Shuttle type vehicle which has both solid and liquid propulsors. The technology for the problem has been learned but the models must be tuned for the Space Shuttle and its unique characteristics.

This study performed and used the results of a preliminary climatological diffusion assessment to define the problems involved in performing a full scale assessment; therefore, these preliminary air quality results should be used with extreme caution in drawing conclusions regarding the environmental effects of the Space Shuttle exhaust effluents.
Environmental impact evaluation will be based on calculations of the ground level concentrations using the NASA/MSFC Rocket Exhaust Effluent Diffusion (REED) Description (1,2) input data for each selected meteorological regime. The use of the REED Description for environmental assessment requires a detailed knowledge of the surface mixing layer. The thermodynamic and kinematic properties of this layer can be measured with radiosondes, tetroonsonde, and other instrumental platforms. Large samples of these data are required for a climatological assessment of environmental impact. The only data set available which is sufficiently large to satisfy this requirement was obtained from radiosondes. These data were obtained daily (at 0000Z and 1200Z) at KSC for more than fifteen years by the U.S. Air Force Air Weather Service. In addition, four soundings per day were taken during a five year period (1962 through 1966).

The tapes containing the radiosonde data will be scanned and subsets of profiles will be established which correspond to the various meteorological regimes that were developed for air quality assessments by Stephens and Sloan (3). These data subsets will ultimately be used as input to the REED Description for calculation of air quality impact.

The data to be used will be the KSC soundings from the period 1962 - 1966(*). The sample cumulative probability distribution of maximum ground-level concentrations attributed to each meteorological regime will be calculated; these probability distributions will be useful for estimation of the probability of exceeding a specified maximum concentration for a particular regime.

(*)The data tapes were obtained from the U.S. Air Force Range contractor, Pan American World Airways.
2.1 SELECTION OF AVERAGE YEAR

Monthly average surface data during the subject period (1962 through 1966) were used for determination of the year which was most representative of normal conditions at KSC. Because of the convenience of obtaining the required summaries from regular NOAA weather stations, climatological data from a similar coastal location (Daytona Beach) 50 miles from KSC were used to represent KSC.

The criterion for selection of a particular year was that it have the smallest value of the parameter $D$ given by

$$D = \frac{1}{12} \left( \sum_{i=1}^{12} |T'_{mi}| + \sum_{i=1}^{12} |T'_m| + \sum_{i=1}^{12} |v'_m| \right)$$

where $i=1$ corresponds to January, $i=2$, February, etc. and $|T'_{Mi}|$, $|T'_m|$ and $|v'_m|$ are the absolute deviation of the monthly mean daily maximum and minimum temperature and monthly mean wind speed from their respective normal monthly means; the quantity $D$ represents the average monthly total absolute deviation for the three parameters.

The calculated values of $D$ are given in the table below.

<table>
<thead>
<tr>
<th>Year</th>
<th>62</th>
<th>63</th>
<th>64</th>
<th>65</th>
<th>66</th>
</tr>
</thead>
<tbody>
<tr>
<td>$D$</td>
<td>4.85</td>
<td>5.30</td>
<td>4.83</td>
<td>3.41</td>
<td>3.65</td>
</tr>
</tbody>
</table>

Thus, the year 1965 was selected as the year most representative of normal conditions at KSC.

In connection with our selection of a climatological data set, the following background data for KSC were acquired from the National Weather Records Center:

- Monthly and annual inversion statistics for the period 1965 through 1969 based on KSC Rawinsonde data
- Monthly and annual STAR summary of atmospheric stability for the period 1965 through 1969 based on Cocoa Beach surface data
Monthly and annual mixing height statistics for the year 1965 based on KSC Rawinsonde data.

With regard to the 1965 KSC Rawinsonde data tape, we intend to calculate the following statistics as a function of time of day:

- Distribution of atmospheric stability calculated between 1.2 to 1.5 km (4,000 to 5,000 ft) by taking the gradient of virtual potential temperature
- Distribution of the height of ground based inversions
- Distribution of wind speed at 1.2 km
- Distribution of wind direction at 1.2 km

These statistics are correlated with the diffusion potential of the ambient air at typical SRB cloud stabilization altitudes. The distribution of the height of ground based inversions is useful in the study of how often SRB clouds are expected to penetrate such inversions and thus become effectively isolated from the ground; ground based inversions are also responsible for the largest concentrations observed at ground level whenever there is a release from a non-buoyant ("cold") source. The distribution of wind direction at the typical height of SRB cloud stabilization chosen (1.2 km) is correlated with the expected track of the SRB cloud at the calculated stabilization height.

2.2 METEOROLOGICAL REGIMES

In support of air quality assessments for aerospace vehicle exhaust effluents at Kennedy Space Center, meteorological regimes were defined which correspond to synoptic patterns (3). These regimes are designed to narrow the air quality statistics into categories that reflect temporal development of atmospheric conditions at launch.
In the past the meteorological inputs to the NASA/MSFC REED Description have been based mostly on climatological statistics until about 12 hours prior to launch, at which time a deterministic forecast was made. An obvious drawback to this approach is that the statistical air quality assessment during the pending launch period, two or four days prior to launch, does not reflect atmospheric dynamics identifiable from current synoptic conditions.

Thus, the purpose of defining meteorological regimes in terms of synoptic conditions is to provide a realistic means of classifying subsets of the overall climatological data set for statistical air quality assessments. Since these subsets are more representative of developing atmospheric conditions during the pending launch period, the use of these subsets assures a smoother interface of the statistical air quality assessment with the deterministic assessment. Employing this classification system, the statistical assessment affords error bounds for the deterministic predictions.

It is necessary to consider the types of atmospheric data sources and the applications for which the results of the diffusion predictions will be utilized in order to define appropriate meteorological regimes. The amount of detail required in the atmospheric kinematics is dictated by the planned application of the diffusion prediction. Two extremes in applications are air quality and deployment predictions. If the diffusion predictions are to be utilized in support of air quality predictions to insure public safety, the detail in the atmospheric input parameter can be relaxed in favor of slightly conservative values which incorporates a safety factor. Since the desire is to identify any potential for an air quality problem, the exact location and concentrations are of secondary importance as long as the error bounds for these estimates have been determined and are reasonably conservative. For this application, routine radiosonde data
are satisfactory since small spatial and temporal changes in the atmospheric kinematics can be neglected without a serious impact on the creditability of the results.

On the other hand, if the application for the diffusion prediction is to support the deployment of the cost-effective rocket effluent monitoring network, the resolution requirements of the atmospheric input parameters for the REED Description are very stringent. This increase of rigor is introduced by the need for exactness in the predicted transit path. In this case, local spatial and temporal changes in the atmospheric kinematics must be considered. This means that terrain effects and the land-sea interface effects must be known. Since the radiosonde provides predominately vertical information, other sources of data must be used to obtain horizontal-temporal information. In general, wind tower data are not adequate to totally support this requirement since the available information is limited to the surface boundary layer. Currently, the best source of local spatial-temporal information is a tetroonsonde (a constant level balloon with radiosonde) flown nominally at 600 meters (4). Other potential means to obtain or improve the local spatial-temporal information would be from simultaneous multiple radiosonde releases or a remote sensing system. Hence exactness in predictions of the exhaust cloud transit path is limited by the state-of-the-art of the available small scale atmospheric measurement system. Extensive meteorological support of the NASA rocket exhaust effluent prediction and monitoring program have been documented for a series of seven Titan launches (5-11); the hydrogen chloride measurements for the same series are described by Gregory, et al. (12)

A common requirement for a diffusion prediction is the statistical air quality assessment for planning activities prior to a launch. The objective is to use these statistical assessments for mission planning activities to optimize launch windows.

2-5
Meteorological regimes needed for air quality assessment prior to launch were defined. The regimes were not intended for detailed launch effluent monitoring support.

Before defining the meteorological regimes, consideration of the selection and sequential nature of the approach will be described. Typically, there are about nine different patterns that could be associated with the weather conditions at Kennedy Space Center. Within each pattern, there are a wide variation in the small scale kinematic and thermodynamic structure depending on the type and intensity of the mesoscale activity present.

It is appropriate to use existing knowledge of seasonal variation at KSC in the selection of seasonal time regimes for statistical analysis. It is apparent that the length of the seasons at KSC are non-uniform with relatively long summers and winters (mid-May through mid-October and December through March, respectively) which are separated by short (approximately 6 weeks) transition periods. It is known that the summer and winter diffusion meteorology will contribute to the largest variation between calculated seasonal environmental impacts; since the realistic seasonal breakdown of data sets increases the size of the winter and summer sample it follows that the comparison of winter and summer will have better statistical reliability.

The approach is to start with the statistical air quality assessment that is normally used in the mission planning activities; initially the seasonal-temporal regimes are defined; that is, the season of the year—winter, spring, summer, or fall—and the time of day—night, morning, afternoon, or evening. Further narrowing of the regime categories will be achieved by sub-division into the following synoptic patterns:

- The Bermuda anticyclone and associated easterly winds.
• Easterly waves and associated strong vertical mixing.
• Westerly waves and associated frontal activity.
• Continental anticyclones and associated northerly winds.

The next step in the process is the qualification of the intensity of the synoptic regime according to nominal "weak" and "strong" categories. Objective criteria will be established for such a qualification.

In summary the regimes established will consist of the following categories:
• Season
• Synoptic regime
• Intensity of synoptic regime
• Time of day

Other regime categories such as thermodynamic or kinematic parameters may be better suited for climatological air quality assessments.

2.2.1 Air Quality Impact and Associated Meteorological Patterns

Air quality impact can be classified according to concurrent synoptic meteorology patterns and air mass types. The relative frequency of occurrence of these patterns during 1965 at KSC has been calculated. NOAA synoptic charts drawn twice daily (1 a.m. and 1 p.m. EST) were used for the analysis. The following synoptic and air mass classification was used:

<table>
<thead>
<tr>
<th>Synoptic Type</th>
<th>Synoptic Class</th>
<th>Air Mass</th>
</tr>
</thead>
<tbody>

<tr>
<td>D</td>
<td>Continental Anticyclone</td>
<td>Continental Polar (CP)</td>
</tr>
</tbody>
</table>

(1) Specification of the air mass type for Type C is dependent on the type and strength of the front (cold, warm, stationary) and its location relative to KSC.
This classification is essentially the same as that
given in Reference 1 with slight modification of synoptic
Type A to represent the general category of maritime anticyclones which is composed of two seasonal sub-types. In
summer the maritime anticyclone is synonymous with the
Bermuda anticyclone which persistently dominates the weather in the Eastern United States. The only break in this persistent
pattern occurs in late summer when inverted low pressure
troughs embedded in the tropical easterlies move to the vicinity of KSC (Type B, Easterly Wave). These troughs are in rare
instances associated with a hurricane. In winter, anticyclones containing cold dry air move southeastward toward KSC; as
these circulations pass over the relatively warm water east of the Florida peninsula, they are rapidly modified. Thus,
in winter, there is a typical alternating pattern of Type A and Type D anticyclones. The transition between the two types is characterized by Type C (Westerly Wave) conditions which include clouds and precipitation associated with fronts and eastward propagating waves in the westerlies (Type C, Westerly Wave).

The monthly and annual percent occurrence of the various synoptic regimes and air mass types during 1965 is
given in Table 2-1. It is clearly indicated that the predominant synoptic regime is the maritime anticyclone (Type A) with an annual occurrence of 57.6 percent; on a monthly basis Type A predominated during the period March through November. During the winter months (December through February) continental anticyclones are often strong enough to penetrate far enough southward to become the predominant synoptic Type D at KSC. The occurrence of air mass types is correlated with the occurrence of the synoptic types.

It is obvious from the analysis that the summer season is the most critical in the assessment of environmental...

Synoptic Types:
- A = Maritime Anticyclone
- B = Easterly Wave
- C = Westerly Wave
- D = Continental Anticyclone

Air Mass Types:
- CP = Continental Polar
- MT = Maritime Tropical
- MT-CP = Transitional Air Mass
impact in populated areas west of KSC. During this period Easterly flow associated with the maritime (Bermuda) anticyclone will occur during a large percentage of the time. During the daytime, the synoptic flow is enhanced in the surface layer by the local sea-breeze circulation. As the air associated with the sea-breeze circulation moves onshore, a ground based mixed layer develops. The thickness of the mixed layer is a function of the intensity of turbulence generated by mechanical interaction of the air with the land surface roughness elements and land-to-air heat transfer. It is hypothesized that concentrations of SRB effluents may occur at ground level locations in areas west of KSC when portions of the stabilized SRB cloud are within the sea breeze mixed layer. This hypothesis will be tested in a planned study based on the available sample of Rawinsondes obtained during the period 1100 to 1500 EST during the summer months (June through September) of 1965. The sub-sample of soundings which exhibit a well-developed sea breeze and a mixed layer extending above the stabilized SRB cloud will be used as input data to the UNIVAC 1108 REED Description. The calculated maximum concentrations and dosages will be compared with those calculated at times of the year during different meteorological regimes and times of the day. If the hypothesis is verified for the 1965 data, a more detailed analysis will be initiated based on the additional summer soundings that can be drawn from the existing data tapes for the year 1962 through 1964 and 1966. The results of this study will comprise the maximum estimated impact, assuming that there are no launch constraints based on air quality impact considerations.

During summer nights, the land breeze will tend to be minimized, since it is opposed by the large scale synoptic flow; it is during this period when the flow is poorly organized that the forecasting of SRB cloud trajectory will be the most difficult. However, calculated downwind concentrations during
the night are not expected to be as large as those during the
day because of the decreased rate of vertical diffusion
associated with the tendency of the atmosphere near the ground
to become neutral or stably stratified during this period.

The idea that a representative sub-sample of meteorological data can be drawn from a larger sample was tested
by comparing percent occurrence of synoptic and air mass types
during 1965 for 102 cases (based on two NOAA synoptic charts
per day at 1 a.m. and 1 p.m. EST for one day per week for 51
weeks) to that obtained for 726 cases based on twice daily
data for 363 days. The results of this comparison are given
in Table 2-2. It is indicated that the statistics of the sub-
sample in most categories correspond closely to those of the
parent sample. The only significant deviation is for the
occurrence of synoptic Type C which is underestimated in the
sub-sample. This can be attributed to the fact that Type C
is a transient phenomena that is not accurately seen by
weekly sampling.

2.3 PRELIMINARY RESULTS FROM 1969 METEOROLOGICAL DATA SPACE SHUTTLE CLIMATOLOGICAL DIFFUSION ASSESSMENT

A preliminary climatological assessment study was begun using 1969 meteorological data and effluent parameters given in the Agency Environmental Impact Statement for the Space Shuttle (13). A sample of 101 soundings (one day per week and 2 soundings per day) were generated from a 1969 met data tape using the met screening program. With the aid of the AEC and TVA stability criteria output by the program for each sounding, the height of the surface transport layer was chosen and input cards for the pre-processor were assembled. The 101 cases were then run through the multi-layer/pre-processor system and the results tabulated. Table 2-3 shows the two worst cases of the 101 processed. The November 16th case is further illustrated in Figure 2-1. Note that for January 8, the maximum dosage approaches the critical NAS level (2400 PPM-sec) as does the maximum peak concentration for November 16 (critical NAS level = 8 PPM)(14).

Figure 2-1. Maximum Predicted (Model 4) Ten-Minute Time Mean Ground-Level Centerline HCl Concentration (PPM) for a Normal Space Shuttle Launch (Rawinsonde Input Data for 11/16/69, 12Z).
Examination of data obtained from towers at various locations at KSC has indicated that surface* temperatures can be highly variable. This variability leads to a degree of uncertainty in the diffusion calculations, which are usually based on data obtained at one location. To illustrate this uncertainty the diffusion calculation for the worst case maximum centerline HCl concentration (11/16/69, 12 Z) was repeated using a revised surface temperature of 0°C which was 7°C colder than the original temperature. This temperature difference is within the expected range of variability of surface temperatures at KSC. The results are illustrated in Figure 2-1 (original calculation, surface temperature = 7.0°C.) and Figure 2-2 (revised surface temperature = 0.0°C). It is shown that the revised maximum concentration increased to 6.92 PPM from the original value of 5.03 PPM; the maximum dosage increased from 719 to 831 PPM-sec for the revised data. It is concluded that surface temperature uncertainties in the input meteorological data lead to uncertainties in the calculated air quality impact. Other workers have indicated an uncertainty of as large as a factor of two in the diffusion model results, largely attributable to meteorological uncertainties. However, field measurements taken after TITAN launches (1) suggest a significantly smaller uncertainty (10 to 25 percent).

In view of the uncertainties in the calculations and the limited sample of KSC meteorological data uses, the results for peak concentration described below are considered very preliminary.

By comparing the peak concentration data to NAS standards the following categorization scheme was devised by Dr. Stephens for mapping of the results. Future results based on a large data sample will use the color categories given below:

* Actual height about 2m above surface.

2.3.1 Air Quality Guidelines

The climatological air quality assessment of the impact of the Shuttle SRB exhaust cloud requires the comparison of ground-level concentration and dosage predictions to air quality guidelines given by the National Academy of Sciences (NAS), with the exception of industrial standards applicable to KSC which assume chronic exposure. There are no national standards for the short-term exposures associated with aerospace exhaust effluents (Ref 14). A graphical illustration of how a statistical summary of dosage predictions can be compared with an NAS guideline for aerospace applications is given in Figure 2-3. The particular NAS guideline used in the illustration is the short-term public limit for a 10-minute average exposure (STPL 10) which is 4 parts per million (ppm) for HCl with an 8 ppm ceiling. This is equivalent to a dosage of 2400 ppm-sec. The cumulative distribution of maximum 10-minute dosages (expressed in percent of 2400 ppm-sec) predicted by the NASA/MSFC REED Description for 101 cases during 1969 is plotted in Figure 2-3. It is shown that 98 percent of the predicted dosages were less than 34 percent of the NAS standard. The largest predicted dosage was 2176 ppm-sec (January 8, 1969), which was 91 percent of the NAS standard. These results are preliminary. Additional calculations, based on an updated diffusion model, the objective methods for specification of the standard deviation of wind azimuth angle (SIGAR) and transport layer height, and the large sample of data available for 1965 (>1400 cases) will be made as the study continues.

Initial indications suggest that the Space Shuttle does not have an air quality problem under normal atmospheric conditions. However, marginal air quality conditions could exist within KSC which could result in a requirement for crowd control.
Figure 2-3. Cumulative distribution of maximum predicted 10-minute dosage expressed in percent of NAS short-term public limit (STPL). (Preliminary result based on 101 cases calculated from KSC Rawinsonde data at 00Z and 12Z)
2.3.2 Transport Direction of the Stabilized SRB Cloud

The statistics of expected transport direction of the stabilized SRB exhaust cloud give an indication of the direction where significant impact is most probable (assuming no meteorological launch constraints with regard to expected air quality impact). A preliminary evaluation of the distribution of SRB exhaust cloud transport, based on 101 cases in 1969, is illustrated in Figure 2-4. The transport direction was estimated from Rawinsonde data by taking the wind direction at the altitude nearest the cloud stabilization height. In more than 70 percent of the cases this altitude was within 100 meters of the cloud stabilization altitude. For the other cases, examination of the wind direction profile did not justify interpolation to obtain a better estimate of wind direction. Transport direction is taken as 180 degrees plus the wind direction. Thus an east wind (90°) results in a westward transport direction (270°). It is shown that the transport directions with the largest calculated frequency of occurrence (12 percent) were east-southeast and northwest. Further comments on transport direction statistics are reserved for forthcoming calculations based on larger data samples. The distribution of transport direction at KSC will be derived as a function of time of day (0100, 0700, 1300, 1900 EST) for the 1965 transport directions for each time of day that can be obtained using the 1965 data.
Figure 2-4. Transport direction at cloud stabilization height expressed in percent occurrence. Based on weekly Rawinsonde data obtained twice daily (00Z, 12Z) during 1969 (101) cases.
NEW OBJECTIVE CONCEPTS

A portion of this study effort was spent in exploring new concepts for the objective analyses of the meteorological data. These objective analyses, if proven by theory and test, would allow the automatic selection of REED Description parameters. That would lead not only to a large savings in man-power but to a better, more uniform treatment of the data.

2.4.1 Transport Layer Height Determination

An attempt to develop objective criteria for selection of the transport layer height used in the NASA/MSFC Multilayer Diffusion Model has been made. Acceptable criteria will permit the development of a computer code for the automation of transport layer height selection. Although an acceptable set of objective criteria have not yet been found, preliminary criteria have been established and are being tested.

Two sets of criteria listed in Tables 2-4 and 2-5 were studied. The relative frequency of occurrence of the various transport layer categories are also given in the tables. In the first set of criteria, outlined schematically in Figure 2-5, strong emphasis is placed on the existence of stable layers below the cloud. This results in a large number of transport layer heights below cloud stabilization height, which in effect reduces calculated ground level concentrations by reducing the amount of cloud mass which can be diffused downward. If these stable layers are proven to have a smaller frequency of occurrence because of inaccuracies of the Rawinsonde data or are not related to actual transport layer heights, the calculated air quality impact will not be conservative. In the present stage of development of our capability to predict air quality impact, it is not desirable to use techniques that may later be proven unconservative.

The criteria listed in Table 2-5 will give conservative results because emphasis is given to the occurrence of wind
Figure 2-5. Typical Temperature Soundings for Various Mixing Depth Categories of Transport Layer Height Given by Circled Number.

</table>
shears and stable layers above cloud stabilization height.

A code has been written which executes the logic developed by the H. E. Cramer Co. for selection of the height of the surface transport layer; selection is based on criteria for the vertical gradient of virtual temperature $\Delta T_v/\Delta z$ summarized below:

- A ground based inversion is defined if
  $$\Delta z \geq 100 \text{m and } \frac{\Delta T_v}{\Delta z} \geq -0.005 \, ^\circ\text{C/m}$$

- The base of a stable layer at $z_1$ if
  $$\Delta z = z_2 - z_1 \geq 100 \text{m and } \frac{\Delta T_v}{\Delta z} \leq -0.005 \, ^\circ\text{C/m}$$

where $z_2 > z_1$

If a ground based inversion exists, the height of surface transport layer is specified as the top of the ground based inversion; otherwise it is the height of the base of the first stable layer above the ground. If the base of the first stable layer is above 3000m the depth is set equal to 3000m.

The code will be used for specification of the surface transport layer for the 1965 Radiosonde data (>1400 cases). The calculation of transport layer height, $H_m$, will be made concurrent with the calculation of the stabilization height, $H_s$, of the SRB cloud. A criteria will be established to identify cases when calculated downwind concentrations and dosages are essentially zero. These cases are associated with a very low transport layer height relative to cloud
stabilization heights. The criteria would be of the form

\[ H_s - H_m > X \]

where \( X \) would be selected on the basis of a sub-set of diffusion calculations for various values of \( H_s - H_m \). The results of these calculations can be illustrated hypothetically as shown in Figure 2-6; based on this hypothetical example \( X \) would be chosen to be 400 meters.

The criteria would be used to eliminate trivial cases from the large parent sample.

2.4.2 Bivariate Normal Wind Distribution

In addition to the other analyses of the 1965 data, a study of the theory of the bivariate normal distribution and its use in summarizing the wind statistics at KSC was conducted. The theoretical equations and derivation supplied by O. E. Smith of NASA/MSFC were checked out, and the essential equations have been coded. Given the bivariate normal statistics, the program outputs the following:

- The distribution of wind direction.
- The distribution of wind speed given a specific direction (15).

Since the monthly bivariate normal statistics have already been calculated for KSC, the programs developed would be used as part of our operational forecasting scheme.

2.4.3 Development of Objective Methods for Estimation of Meteorological Input Variables for the Multilayer Diffusion Model

The development of objective methods for the estimation of meteorological input variables for the Multilayer Diffusion Model requires the following:
Figure 2-6. Hypothetical schematic representation of relation between air quality impact of SRB cloud and the difference between cloud stabilization height and transport layer height ($H_S - H_m$).
Establishment of a theoretical basis for the method,

Development of computer codes for calculation of the standard deviation of wind azimuth angle over a ten-minute period (SIGAR) and for specification of height of the transport layer (H_m),

Testing the computer codes for a climatological data sample,

Modification of the preprocessor to include the new codes.

The theoretical basis (16) for the method selected for estimating SIGAR is based on solution of equation

\[ \text{SIGAR} = \frac{\sigma_v}{U} = \frac{k f(B)}{\ln \frac{z}{z_o} - \psi(RI)} \]  

where \( \sigma_v \) = standard deviation of the lateral component of turbulence (m/sec)

\( U \) = mean wind speed (m/sec)

\( z_o \) = roughness length (m)

\( k \) = Von Karman's constant = 0.4 (dimensionless)

The function of Richardson number, \( \psi(RI) \), for unstable conditions is

\[ \psi(RI) = 2 \ln \left[ \frac{(1+x)/2}{(1-x)} \right] + \ln \left[ \frac{(1+x^2)/2}{(1-x^2/2)} \right] - 2 \tan^{-1} x + \pi/2 \]  

\[ \text{where} \quad x = (1-16RI)^{1/4} \]  

(2a)
For stable conditions (17)

\[ \Psi(\text{RI}) = \frac{7 \text{RI}}{1 - 7\text{RI}} \]  

(3)

The right side of Equation 1 was derived (16) by substitution of expressions for \( \sigma_v \) and \( U \) given below for the ratio \( \sigma_v/U \).

\[ \sigma_v = \mu f(B) \]  

(4)

\[ U = \frac{\mu}{k} \left[ \ln \frac{z}{z_0} - \Psi(\text{RI}) \right] \]  

(5)

where \( \mu^* \) is the friction velocity, and the function \( f(B) \) is accurately approximated by fitting line segments to experimental measurements of the ratio \( \sigma_v/\mu^* \) according to,

\[
\begin{align*}
2.7 & \quad B < -0.008 \\
2.7 + 112(0.008+B) & \quad -0.008 \leq B < -0.00175 \\
3.4 - 725.5(0.00175+B) & \quad -0.00175 \leq B < 0.0008 \\
1.55 + 38.04(B-.0008) & \quad 0.0008 \leq B < 0.029 \\
2.35 + 5.43(B-.029) & \quad 0.029 \leq B
\end{align*}
\]

6

The Richardson number, \( \text{RI} \), is defined by

\[ \text{RI} = \frac{g \frac{\partial \theta}{\partial z}}{\left(\frac{\partial v}{\partial z}\right)^2} \]  

(7)

where \( g = \) acceleration of gravity \( (\text{m/sec}^2) \)

\( t = \) absolute temperature \( (^\circ\text{K}) \)

\( \frac{\partial \theta}{\partial z} = \) vertical gradient of potential temperature \( (^\circ\text{K}/\text{m}) \)
\[ \frac{\partial v}{\partial z} = \text{vertical gradient of wind speed (1/sec)} \]

The quantity \( \frac{\partial \Theta}{\partial z} \) can be expressed as a function of pressure and vertical gradient of temperature according to

\[
\frac{\partial \Theta}{\partial z} = \frac{\Delta \Theta}{\Delta z} = \left( \frac{1000}{P} \right)^{288} \left( \frac{\Delta t}{\Delta z} + .0098 \right)
\]

(8)

where \( P \) is the pressure in millibars.

Since available wind measurements are not sufficiently accurate for estimation of the denominator in Equation (7), it is necessary to estimate \( R_I \) from measurements of the non-dimensional stability ratio, \( B \).

\[
B = \frac{g \bar{z}^2}{\tau U^2} \frac{\Delta \Theta}{\Delta z}
\]

(9)

where, \( \bar{z} \) = the geometric mean height (m) between the top and bottom of the layer considered (17)

\( U \) = mean wind speed in this layer (m/sec)

The relation (17) between \( B \) and \( R_I \) is

\[
R_I = B \left[ \frac{\ln z_0}{\phi(RI)} - \Psi(RI) \right]^2
\]

(10)

where, \( \phi(RI) = (1-16RI)^{-\frac{1}{4}} \) for unstable conditions

(11)

\[ \phi(RI) = \frac{1}{1 - 7RI} \] for stable conditions

(12)
For stable conditions it can be shown that Equation (10) is a quadratic function of the parameter y.

\[ y^2 + y/7kB^{1/2} - (k+1)/7k = 0 \]  

(13)

where, \( y = (RI)^{1/2} \)  

(13a)

\[ k = \ln(z/z_o) - 1 \]  

(13b)

For unequal real roots, the root given by the following equation will result in physically realistic calculated values of RI over the expected range of measured values of B.

\[ y = - \frac{1}{14k\sqrt{B}} + \frac{1}{2} \sqrt{\frac{1}{49k^2B} + \frac{4(k+1)}{7k}} \]  

(13a)

\[ RI = y^2 \]  

An additional constraint is required to assure that physically realistic values of RI are calculated for stable conditions; examination of Equation 12 reveals that a singularity exists for RI = 1/7. The singularity is eliminated by assuming \( \phi(RI) = \phi(0.137) \) for RI ≥ 0.137. This constraint is implemented only in rare instances during extremely stable conditions. This problem is also evident in Golder's nomogram (17) for estimating RI from B; the RI scale on the nomogram has a maximum value of ~0.13.

For unstable conditions Equation 10 can be written as

\[ 1-x^4 \]  

\[ \frac{16x^2}{lnz/z_o+0.50864-2[ln(1+x)]-ln(1+x^2)+2 tan^{-1}x} \]  

(14)

where \( x \) is given by Equation 2a. Equation 14 is solved by Newton's method.
The methodology for calculation of SIGAR can be summarized as follows:

- Calculate $B$ from available tower or Rawinsonde data (Equation 9)
- Evaluate $F(B)$ (Equation 7)
- Specify $z_A$. A reasonable first approximation is $z_A = 0.25\text{m}$ (18)
- Solve Equation 13 or 14 (unstable or stable conditions) to obtain $RI$ from Equation 11 or 13a respectively.
- Calculate SIGAR from Equation 1.

Preliminary calculations using Rawinsonde data and data constructed for the purpose of comparison with Cramer Co. SIGAR values (19) are given in Tables 2-8 and 2-9 respectively.

Table 2-6. Calculations of SIGAR using Rawinsonde data between the surface and the first standard pressure level (1,000 mb) with $z_A = 0.25\text{m}$.

(1) \(\Delta T\) measured between 3m and 60m.

(2) SIGAR is the standard deviation of the wind azimuth angle measured over a 10-minute period.

(3) Very stable conditions cannot occur with KSC with such large wind speeds.
Testing of the computer code for SIGAR using the 1965 KSC Rawinsonde data has begun. Preliminary results for January and February data are summarized in Tables 2-8 and 2-9. Table 2-8 indicates that none of the computed values of SIGAR were less than 3 degrees, very few were greater than 18 degrees and most were between 6 and 9 degrees. Table 2-9 indicates that for a particular potential temperature gradient, SIGAR increases with decreasing wind speed. Table 2-9 should be expanded to cover more wind speed and potential temperature gradient intervals as the calculations based on all the 1965 data become available.

2.5 MODIFICATION TO THE UNIVAC 1108 VERSION OF THE REED DESCRIPTION AND THE CLOUD RISE PROGRAM

In the area of climatological assessment, one of the major tools is the NASA/MSFC REED Description (2). In the original mode of operation, a pre-processor program was required to read the meteorological data and calculate cloud rise and cloud location. This process has been automated so that the two programs are executed in one job stream. Instead of punching cards, the cloud rise program builds a disk file where each case processed is given a unique identifier. The REED program then executes with the capability of choosing any of the cases from the cloud rise file in any order. Additional flexibility is achieved by allowing the user to override any parameters set by the cloud rise program prior to the execution of the REED Description.

For the purposes of documentation and compact storage, the capability to produce a duplicate copy of all printer output on plot paper was added. This plotter output is much more suitable than printer output for 8½ by 11" documents, and is also more easily filed. In addition, the tapes from which these plots are made can be saved and used as data files from which additional calculations can be performed.

Finally, the capability to print a table summarizing the most critical parameters for each case in a particular run was added to the code. Thus in a run where many cases are processed, the user can quickly determine which cases are the more critical. This table can be conveniently used directly for documentation purposes.
2.5.1 Screening Program Modification

Modifications to provide additional capabilities for the Meteorological Data Screening Program* were completed. The MET Screening reads in cards, which indicate which soundings to search for, and reads from met data tapes, then it generates as output, plots, cards, and printout for each sounding processed.

The plots include a list of the cloud rise heights plus the following plots:

- Wind Speed versus Altitude
- Wind Direction versus Altitude
- Dry Bulb and Potential Temperature versus Altitude
- Temperature, Virtual Temperature, and Virtual Potential Temperature versus Altitude

The card output from the Screening Program is punched in the format needed for the pre-processor.

The printout has been expanded to include stability criteria. The data were tested against both TVA and AEC stability criteria. The results are printed in a table after the original output has been completed for each time. The following information is printed: The altitude interval, temperature interval, DTODS, AEC stability, potential temperature interval, DPTODZ, and TVA stability. DTODZ is defined as

$$\frac{T_i - T_{i-1}}{Z_i - Z_{i-1}}$$

where $i = 1$ - no. of altitudes

$T$ is temperature ($^\circ$C)

$Z$ is altitude (meters)

DPTODZ is defined as

$$\frac{PT_i - PT_{i-1}}{Z_i - Z_{i-1}}$$

$PT$ is potential temperature

*Initially developed by Dr. Stephens and W. C. Campbell at MSFC.
The AEC and TVA stability criteria is listed in Table 2-10. This added printout aids in choosing the height of the surface transport layers needed for input into the cloud rise program.

2.5.2 Addition of New Vehicle and Updating of Constants

The characteristics of the newest solid motor in the Thor-Delta family of launch vehicles were added to the Multi-layer/pre-processor system. This new vehicle is known as the Thor-Delta 3914 and is the fifth vehicle that can be simulated by the code.

In conjunction with determining the values for constants associated with the 3914, the same constants were examined for the other four vehicles. These constants include the following:

- QC1, QC2, QC3 - total source output rates (g/sec) for the three types of launch respectively (i.e. normal, abnormal with one motor burning on the pad, abnormal where motors explode and burn on the ground).
- QT1, QT2, QT3 - total source strength (g) for the three types of launch respectively.
- HEATN, HEATM, HEATA - Heat output (cal/g) for the three types of launch respectively.
- a, b, c - Rocket rise parameters in the equation
  \[ T = az^b + c \]
  where T is the burn time and z is the altitude
- FRQ1 - Fractional distribution of material for HCl, CO, CO\textsubscript{2} and AL\textsubscript{2}O\textsubscript{3}.

Table 2-11 lists the preliminary values determined for these constants:

*Value used in report; other is up-dated reflecting latest result.
The original rocket rise equation $T = a z^b$ was modified to the form $T = a z^b + c$. The constant $c$ was added to take into account the time lapse between ignition and lift-off. The parameters $a$, $b$, and $c$ were obtained from least squares fits of empirical trajectory data. Plots of the trajectories generated by the old values and by the new values were made against the measured trajectories. The results are shown in Figures 2-7 through 2-11. For each of the original four vehicles, the trajectory generated by the new values is closer to the measurement than is the old trajectory.

Since the burn rate for solid propellant motors is influenced by the initial temperature of the propellant, the pre-processor program was modified to take into account this initial propellant temperature. A table of the mean temperatures at KSC for each month was added to the code. Based on the month in which meteorological data was taken, the default temperature is obtained from the table and used to compute a burn-rate factor (where $70^\circ$ is the standard, yielding a burn-rate factor of one). The capability to over-ride this default table was also added to the code, so the initial propellant temperature, if known, can be input to the program.

Various runs were made with the UNIVAC 1108 REED Description/Cloud Rise system to check out all the modifications made to the code; however no production type runs have been performed.

2.6 SURFACE DEPOSITION MODEL

Three major constituents in the SRB and SSME exhaust effluents are Al$_2$O$_3$, HCl, and H$_2$O. The HCl is of prime concern environmentally since it is potentially toxic in the gaseous phase and forms a strong acid in the aqueous phase. Two phases of Al$_2$O$_3$ can exist, the gamma phase which reacts strongly with HCl and the alpha phase which does not. The HCl reacts with and is absorbed by water droplets to form an aerosol. The formation of the aerosol, of course, reduces the concentration of gaseous HCl in the atmosphere. The aluminum oxide absorbs H$_2$O readily; it is used as a drying agent in laboratories. Rain falling through a cloud consisting of the rocket exhaust effluents and the entrained air can react chemically with the HCl and possibly the Al$_2$O$_3$ and can physically interact with the HCl aerosol and the Al$_2$O$_3$. Thus it can be seen that the Al$_2$O$_3$/HCl/H$_2$O system has a large number of physical and chemical interactions that can occur simultaneously. A consistent set of reactions and interactions must be developed to allow the calculation of the HCl and Al$_2$O$_3$ concentrations for a surface deposition model.

The phase of the aluminum oxide in the exhaust is not without question. Early work(25) indicated that the aluminum oxide present in a rocket exhaust is the alpha phase, which does not react with HCl. More recent data(26,27,28) has indicated that some of the gamma phase may be present. This may be important to the surface deposition depending on the aluminum particle size distribution in the rocket exhaust. The SRB exhaust will have relatively large particles; therefore, the amount of gamma phase will be less than found in small motor firings. Of course, for an equal weight, the
number and surface area for small particles is greater than for larger particles. The whole question of Al₂O₃ phase is undergoing intensive investigation and must be considered when developing a surface deposition model.

Using available experimentally measured Al₂O₃ particle size distributions (29) for solid propellant rocket motors of various sizes and making reasonable assumptions as to particle size growth as a function of throat diameter, a particle size distribution for the Al₂O₃ exhausting from the Space Shuttle SRB was determined. This is shown in Table 2-12. At the present time no realistic input to the REED Description surface deposition model is available for use; therefore, these effects, which may be significant for climatological predictions, have been neglected.

2.7 ABSORPTION AND SCAVENGING

Studies have been conducted on atmospheric scavenging of HCl which experimentally determined the washout coefficient (30,31). Washout involves several microprocesses, including the solubility of HCl in raindrops, the diffusion of HCl to the falling raindrops, and the physical parameters which characterize the rain. At higher relative humidities, washout of HCl aerosol must be considered in addition to the washout of gaseous HCl. The Al₂O₃ particles as well as salt or dust particles in the rocket exhaust may act as potential cloud droplet nuclei. The nucleating efficiency of Al₂O₃ particles is unknown at this time. The rain scavenging experimental results must be integrated into the surface deposition model.

The effects of absorption and scavenging, which may be significant for climatological predictions, have been neglected in this study because of the lack of a suitable, acceptable washout coefficient. (27,30,32,33)

2.8 CONCLUSIONS

The long term objective of this study is to establish the relation between weather patterns of various scale and the environmental impact of the Space Shuttle exhaust effluents. To date, the synoptic weather patterns have been categorized and their relative frequency of occurrence have been calculated.

Concurrently the tools for calculating air quality assessments for large samples of KSC meteorological data have been developed. A large sample of Rawinsonde data are available for definition of the variability of calculated air quality assessments over time scales as small as six hours. This variability is associated with such phenomena as the development of the sea breeze and ground based stable layers. These phenomena strongly influence the critical meteorological input variables to the diffusion model.
3. EXHAUST CHEMISTRY

The calculation of the heat content of the plume, or more exactly the heat content of the rocket exhaust effluents, taking into account interactions with the ambient environment, is a well-defined problem. The problem has been attacked for many years by the propulsion community and a set of standard techniques have been devised and published for liquid engine performance and analysis by the Interagency Chemical Rocket Propulsion Group - Joint Army, Navy, NASA, Air Force, (ICRPG-JANNAF) Performance Standardization Working Group (34, 35, 36). The state-of-the-art of analysis for solid motors is not yet as advanced but an ICRPG-JANNAF Solid Performance Working Group has begun work.

The available techniques were adequate for analyzing the plume from the liquid propellant SSME rocket engine and the solid propellant SRB motors. The value of the effective heat release and the exhaust species concentrations were quantitatively satisfactory for both propulsion devices. During this study only the Space Shuttle SRB exhaust effluents were studied in detail. Solid propellant rocket motors have the phenomena of two-phase flow occurring in the combustion chamber, nozzle, and plume. The two phases are not in thermal or velocity equilibrium. In general, the particles, in this case solid and liquid aluminum oxide, are traveling slower than the gas, are at a higher temperature than the gas, and are at a greater flow angle than the gas. These phenomena make the characteristics of a two-phase flow field different than that of a single-phase flow field such as occurs in the liquid propellant SSME.
3.1 TWO-PHASE FLOW PHENOMENA

The analysis of the two-phase flow in the SRB rocket nozzle started with a one-dimensional thermochemical analysis of the solid propellant. As seen in Figure 3-1, when solid propellant combusts, the combustion products are at some pressure, $P_c$, and some flame temperature, $T_c$. The chamber pressure history is governed principally by the amount of burning surface exposed. The desired amount of burning surface (chamber pressure) can be obtained by the geometry of the propellant grain. Figure 3-2 shows the Space Shuttle altitude, Mach number, and Solid Rocket Motor chamber pressure history for the first 70 seconds of flight. As can be seen, the chamber pressure varies from 825 to 580 psia during this portion of the flight. With a knowledge of the propellant composition and the chamber pressure, the flame temperature and the concentrations of the combustion products were calculated as shown in Table 3-1. The flame temperature and the combustion products as a function of time (velocity and altitude are then known) were needed for input to subsequent steps. The calculations were performed on the NASA UNIVAC 1108 with a program written by NASA-Lewis Research Center (38) and modified by SAI.

By means of two-phase characteristic theory, the supersonic portion of the flow field of the SRB nozzle and plume was determined. With reference to Figure 3-1, the supersonic portion is bounded roughly upstream by the nozzle throat and downstream by the plume boundary. The nozzle analysis portion of the program basically terminates calculation along the last left-running characteristic, identified on Figure 3-1. This surface is significant in that no disturbance downstream of it will affect the pressure field along the nozzle wall. The program originally written by TRW personnel (38) and extensively modified by SAI (40) yields vital pieces of information along the last
Figure 3-1. Solid Rocket Motor, Nozzle, and Plume
left-running characteristic which are needed for subsequent steps in the modeling.

A two-phase flow field is dissipative and non-equilibrium in nature. There is, therefore, an entropy rise down the flow field and an entropy gradient radially across the flow fields since the particles and gas have a different history at every point in the flow field. The entropy rise and the loss in total pressure can be calculated from local flow properties. Figure 3-3 shows the total pressure loss and gradient along the last left-running characteristic for the Space Shuttle SRB nozzle with a single particle size of 12.0 micron diameter which represents an average particle size. The pressure loss varies from about 27 to 55 percent of the chamber pressure; thus, the species and energy content of the exhaust will vary across the nozzle exit. Because of the wide variation in properties across the exit, an integration scheme was incorporated into the program which integrates the mass flow and energy content and computes the average for a gross value of the energy content of the exhaust as it leaves the nozzle. The energy content of the exhaust was assumed to be composed of two parts: the sensible enthalpy and the kinetic energy of the gas. For a SRB operating at 780 psia chamber pressure, the average integrated value of the heat content of the plume is 2125 calories per gram. Figure 3-4 is a schematic of the SRB nozzle. The chamber pressure chosen, 780 psia, is an average value representative of the SRB when it is close to the launch pad, 0-3000 meters altitude.

3.2 AFTERBURNING AND MIXING ANALYSIS

Solid propellants normally are formulated to have an exhaust composition rich in underoxidized species, i.e., the carbon, C, is preferentially in the form of carbon monoxide, CO, rather than carbon dioxide, CO₂. This formulation technique gives higher specific impulse for the propellant. A

jet exhausting into a stationary or moving atmosphere tends to entrain and mix the atmosphere with the jet exhaust.

When a hot exhaust with underoxidized species mixes with ambient air, the possibility for afterburning exists. This condition has been noted on several launch vehicles, and digital computer programs have been written to describe the phenomena with varying degrees of success (41-43). Several of the programs appear generally suitable for use in the proposed study. Based on such factors as ease of input, accuracy, computing time, and calculation technique, the program written by AeroChem Research Laboratories, Inc. (43) was chosen. Figure 3-5 shows the plume afterburning schematic as it applied to this situation. The only modification necessary for the program to be used for the problem under consideration is in the description of the the initial data line. The initial data line for the original program is assumed to be radial, normal to the axis at the exit of the nozzle. All species and the velocity at each grid point must be input. The output of the two-phase analysis program is along the last left-running characteristic. The velocity, entropy, and stagnation pressure are known at every point on the characteristic but not the species; therefore, a technique was devised which would fill the gap between the last left-running characteristic and the needed initial value line and which would calculate the species along the initial value line. There exists in general use in the aerothermodynamic community in this country, a computer program known as PLIMP (44) which calculates and outputs the species concentration, pressure, temperature, and velocity fields on surfaces immersed in a plume; therefore, if a flat plate is placed normal to the axis at the exit of the nozzle, all necessary quantities will be obtained.

The Aerochem mixing program calculated the required values of species concentration and amount of entrained air simultaneously. Stedman (27) in his work estimated the
Figure 3-5. Plume Afterburning Schematic
amount of mixed or entrained air from the work of Hart (45) and assumed uniform mixing and chemical equilibrium in the cloud. The Aerochem program not only estimated the amount of entrained air, which is not uniform across the jet, but also determined the species concentrations using finite-rate chemistry. This technique thus detailed the species, the reaction rates, and the temperature and pressure radially across the exhaust as well as in a downstream direction from the nozzle exit. An inventory of the constituents was thus maintained. Table 3-2 lists the reaction scheme utilized in this study. The scheme models the chlorine species production and destruction in detail. Figures 3-6 and 3-7 show the Space Shuttle SRB exhaust effluents as a function of distance from the nozzle exit. Table 3-3 shows the exhaust effluent weight fractions as a function of distance from the nozzle exit.

3.3 OTHER LOSSES

It should be noted a number of potentially important effects were neglected. The first effect neglected was the injection of water into the exhaust. Since the study was initiated, the decision was made to inject large quantities of water into the exhaust as a noise suppression technique. The water is not only to be injected when the Space Shuttle is sitting on the launch pad but the injection will continue until it clears the launch pad. Due to the afterburning and the large number of hot particles, a large luminous plume is formed; therefore, radiation losses may be important. Hart (45) using geometric flight and launch hardware radiant flux estimates, states that the radiation loss may be as large as one-fourth the total heat content. If this estimate is correct, radiation loss calculations are imperative. The radiation data for the exhaust effluents have been collected and tabulated, but the entire calculation has not yet been performed. During the time the SSME's are building up thrust and until shortly after SRB ignition, the Space Shuttle is held onto the launch pad. During this time and even after liftoff, for

a short time, the exhaust effluents are flowing into the flame trench where they are mixed with a large amount of water and ducted away. This mass and energy ducted away represents a possible loss to the ground cloud which may be important. This portion of the problem has not yet been attacked. This study has concentrated primarily on the SRB exhaust effluents and has essentially neglected the SSME exhaust and the problem of the impingement and mixing between the SRB and SSME exhaust plumes. The SSME exhaust effluents have been calculated and are shown in Table 3-4.

3.4 CONCLUSIONS

This study has developed a technique that allows the exhaust effluent chemistry for the SRB to be determined with a state-of-the-art analysis. At this point the basic exhaust effluents have been calculated but a number of important losses such as plume impingement, radiation, flame trench, and water injection have not been addressed. The effluents from the SSME have been determined but the chemical and physical interactions between the two plumes has not been studied.

4. CONVERSION PROGRAMS

In order to allow for the processing of various types of data, received from numerous sources (i.e., Marshall Space Flight Center, Kennedy Space Center, Vandenberg AFB, Point Mugu, Asheville, etc.) and generated on several different computer configurations (i.e., IBM 360, IBM 370, IBM 7094, UNIVAC 1108, CDC 3300 etc.); there becomes a specific need for software which provides the capability of converting the various and voluminous amount of data into the proper BCD/EBCDIC+ASCII character set and record format to make it compatible to the different computer systems (i.e., IBM, UNIVAC, REEDA), upon which the data will be processed by a variety of programs. The data and programs must be available on all NASA/MSFC machines since no machine outage should cause a lack of monitoring capability.

In this section various conversion programs that were developed are discussed. Section 4.1 describes the conversion programs which have generic applications while Section 4.2 discusses conversion programs developed for individual cases. The program listings are given in the Appendix.

4.1 CONVERSION PROGRAMS (GENERIC)

The most efficient means to load data or software on the REEDA System, which was generated on other computer configurations, is to generate a magnetic tape compatible with the REEDA System. The following is a list of the requirements that all magnetic tapes must satisfy to be usable on the REEDA System:

- 9-track magnetic tape
- 800 bits per inch
- Odd parity
- 7-bit ASCII (The 8th bit is always off; this limits the character set to 128 combinations)

however, most (if not all) of the data and software programs being processed on the REEDA System received from other computer
installations were recorded on magnetic tape in a format not compatible with the REEDA System. Thus, various conversion programs were generated to convert data recorded on IBM, UNIVAC, CDC, etc., computers to a usable format.

4.1.1 IBM 370/360 BCD + ASCII Conversion Programs

A conversion program was developed to convert data or programs recorded in BCD (on cards or magnetic tape) to a usable REEDA System ASCII character set. This program is written in IBM assembly language and will execute on either the IBM 370 or 360 configuration. It will accept as input either a 7-track or 9-track tape, or punched cards and convert each BCD character into a 7-bit ASCII character compatible with the REEDA System. This converted data is written onto a magnetic tape for REEDA utilization (i.e., 9-track, 800 BPI, ODD parity). An example flow of the conversion process is given in Figure 4-1. Note, only the control cards change when running this program on the IBM 370 or IBM 360.

Figure 4-1. IBM 370/360 BCD + ASCII Conversion Process
4.1.2 IBM 370/360 EBCDIC → ASCII Conversion Programs

A conversion program was developed to convert data or programs recorded in EBCDIC (on cards or magnetic tape) to a usable REEDA System ASCII character set. This program is identical to the BCD → ASCII conversion program except all EBCDIC characters are converted to ASCII. As shown in Figure 4-1, input can be either cards or magnetic tape with the output being a REEDA compatible 9-track ASCII tape. Once again only the control cards change from the IBM 370 and IBM 360 programs.

4.1.3 UNIVAC 1108 BCD → ASCII Conversion Program

A conversion program was written in UNIVAC assembly to allow for the conversion of BCD record data on the UNIVAC 1108. As with IBM conversion, data is accepted from either cards or 7-track or 9-track magnetic tape. Each character is then converted to the corresponding 7-Bit ASCII character. A REEDA System compatible 9-track ASCII tape is generated as shown in Figure 4-2.

Figure 4-2. UNIVAC 1108 BCD → ASCII Conversion Process
4.1.4 UNIVAC 1108 EBCDIC \(\rightarrow\) ASCII Conversion Program

A conversion program was also written in UNIVAC assembly language to allow for the conversion of EBCDIC recorded data on the UNIVAC 1108. This program is identical to the BCD \(\rightarrow\) ASCII conversion program except all EBCDIC characters are converted to ASCII. As shown in Figure 4-2, input can be either punched cards or magnetic tape with the output being a 9-track ASCII REEDA compatible tape.

4.2 CONVERSION PROGRAMS (SPECIFIC)

All of the generic BCD/EBCDIC conversion programs allow data to be converted from card/tape to REEDA System compatibility in a one-pass operation. However, the conversion programs were developed with a prerequisite that all data records be 80 characters long (i.e., card size). Thus, in the event records being converted (from tape) are not card images, that is, longer or shorter than 80 characters, a pre-processor is needed to reformat the data into 80 character records. This data can then be used as input into the BCD/EBCDIC conversion programs as shown in Figure 4-3.

![Diagram](image)

Figure 4-3. Reformatting to 80 Character Records Then Converting BCD/EBCDIC \(\rightarrow\) ASCII

Here the reformatter programs were developed to reformat various data from KSC, JSC, Pt. Mugu, Vandenberg AFB, etc., generated on IBM 7094, IBM 360, CDC 3300, UNIVAC 1108, etc., computers to REEDA compatibility. These programs are discussed in Chapter 5.
4.2.1 HP EBCDIC + ASCII Conversion Program

A conversion program was written in HP assembly language to translate IBM 9-track, ODD parity, EBCDIC recorded tapes to the compatible HP format. The program is capable of converting all IBM EBCDIC characters into their 7-Bit ASCII equivalent. Each 32 bit IBM integer is translated to a 16 bit HP integer, and 32 bit IBM real numbers are translated into the HP 32 bit real number format. For this program, the user must define the record lengths and blocksize to the conversion program which then translate the tape as it is being processed. Since only one tape drive exists for the current REEDA configuration, it is not possible to convert the entire tape and rewrite it to another tape for subsequent processing, thus the UNIVAC 1108 and IBM 370/360 conversion programs prove more efficient in most instances.

4.2.2 1965 KSC Rawinsonde Data Conversion Program

The conversion of the 1965 KSC rawinsonde data tapes (18 tapes, four recordings a day for twelve months) for REEDA usability was performed. The BCD to ASCII conversion program for the UNIVAC 1108 was utilized to convert from 7-track to the 9-track REEDA format. In initial attempts to process the data, once it was converted to REEDA System format, it was noted (see Table 4-1) that a non-standard method of recording negative numbers was used when recording the original data. That is, a negative number was represented by over punching an (11) in the right most digit of the variable field. Thus, for the numeric values of 0 - 9 together with an (11) punch would give the visual representation as follows:

</table>
Thus a program was developed to process the data tapes to restore the number back to usable numeric notation. These tapes were then used as input to the REEDA System to build a "single tape" data base containing all pertinent information from the existing 18 tapes. The "single tape" data base allows the user easier/faster access to any/all data which he desires to process, thus eliminating the need to keep a library of 18 tapes and the processing of data which is not desired (See Figure 4-4).

The "single tape" data base was created by processing each of the 18 tapes and eliminating all data above 20,000 feet in altitude for the standard and mandatory levels, thus eliminating a large portion of the data. This data base was updated after each tape was processed with an EOF (end-of-file) mark inserted at the end of each month. Thus a user can easily access any month from the "single tape" data base by skipping the appropriate number of files. It must be pointed out that the initial idea of a "single tape" data base actually turned out to be two tapes containing all selected information from the original 18 tapes. The first tape contains JAN - JUN 1965, while the second tape contains JUL - DEC 1965.

It should also be noted that each of the 18 tapes being processed require about 2 hours to process on the REEDA System. Thus the initial creation of the "single tape" data
Figure 4-4. 1965 Rawinsonde Data Base Generation and Processing
base was quite time consuming, yet since it occurred only once, while the end product (i.e., "single tape" data base) is being utilized quite frequently. The overall effect of the "single tape" data base for the REEDA System is to allow the user to feasibly process all or as much of the 1965 KSC Rawinsonde data as efficiently and as fast as possible and to eliminate the handling of unneeded and unusable data.

Various programs are now being developed to extensively process the 1965 data, such as MOD3B, METPL, and STAN5 which are all documented in Chapter 5.

4.2.3 1974 Vandenberg Rawinsonde Data Conversion Program

The 1974 Vandenberg AFB Rawinsonde data tape contained two soundings per day (0000Z and 1200Z) for the entire year. The initial task was to convert the data into a usable format for the REEDA System. The original tape was generated on an IBM 360/44 and had variable length/variable block size records with half word alignment. A preprocessor was written in FORTRAN to restructure the data into fixed length records to be used as input into the IBM 370 ECBDIC + ASCII conversion program. It was discovered that two types of data records existed on the tape, 1) PIBAL and 2) Rawinsonde. However, neither data record contained all the information that was required to process the data using the REEDA diffusion model program MOD3A. The Pibal record contained pressure, altitude, wind speed, wind direction but not temperature. The Rawinsonde records contained pressure, altitude, temperature, dew point, but not wind speed or wind direction. Subsequently, code was generated to merge the two records by means of various interpolations and calculations. The program computed the best possible values at the nearest altitude, pressure, and temperature. Figure 4-5 gives a brief flow of operations for processing the 1974 Vandenberg AFB data.
Once the data was converted to a usable format for the REEDA System, the program MOD3B was used to process the data. It should be noted that the two soundings per day for the entire year of 1974 were contained on the initial Vandenberg AFB tape. Some 48 cases roughly a week apart at 1200Z hours were processed. The program MOD3B is identical to the program MOD3A except it operates on the Plasmascope, which is interfaced into the REEDA System. It allows faster processing due to the use of "Touch Panel" program options. The output of MOD3B was 48 center line concentration plots and 48 isopleth plots (see Figure 4-6 and 4-7 respectively). This same data will also be processed on the REEDA System utilizing the new version of the program MOD3A.

Figure 4-7. Vandenberg AFB Isopieth Contour Plot
4.2.4  1964 - 1970 Jimsphere Data Conversion Program

A conversion program was written in FORTRAN to convert three meteorological data tapes, (1964 - 1966 KSC, 1967 - 1970 KSC, 1965 - 1970 Point Mugu) containing Jimsphere wind data, to the REEDA System compatibility. The tapes were initially created on an IBM 7094 with 36 bit word and data written in both fixed point and floating point binary. Each record contained 298 words with 20 such records per file. Additionally, each tape contained from 266 to 294 files. The decision was made to only extract and convert the needed data to eliminate the cumbersome task of processing over and around data not needed for calculations. Only the time, date, altitude, wind direction, and scalar wind speed was deciphered from the original data. It should be noted that the wind speed and wind direction were recorded at equal intervals in altitude from 25 meters to 20,000 meters. Thus, some 800 data points for both wind speed and wind direction were recorded for every Jimsphere profile.

The conversion program was written for the UNIVAC 1108 utilizing both ENTRAN and ENCODE features to convert the tapes into a format usable by the previously built EBCDIC and ASCII program. This encompassed converting from 36-bit to 16-bit HP word size, restructuring data into 80 character fixed length records, eliminating unwanted data, and then converting to ASCII format as shown in Figure 4-8.

As can be seen, a program to process the Jimsphere wind data on the REEDA System was created called JIMPL which will be discussed in Chapter 5.
Figure 4-8. Jimsphere Data Conversion and Processing
4.3 CONCLUSIONS AND RECOMMENDATIONS

These conclusions and recommendations are based on the conversion programs documented in Sections 4.1 and 4.2 respectively. In reviewing the generic conversion programs that were developed, it seems that they have proven quite satisfactory in providing a mean for converting non-standard REEDA formatted data into a usable form. Data generated on almost any other computer configuration, either 7-track or 9-track, either BCD or EBCDIC, either fixed or variable length records, can be made compatible to the REEDA System via one or a combination of two or more of the conversion programs that have been developed. However, it is still probable that data will be acquired that cannot be directly converted by using just the available conversion programs to date. Consequently, additional conversion programs undoubtedly will be developed as required.

It is also recommended that in most instances, tape reformatting and tape converting be conducted on a large scale computer configuration where multiple tape drivers and faster operating speeds are available.
5. INTERACTIVE REEDA PROGRAMS

In this section all of the applicable interactive REEDA programs are discussed. A brief description, along with current and future applications of each program is given. The following is a list of all the current REEDA programs which are discussed in Sections 5-1 thru 5-7.

- MOD3A
- MOD3B
- METPL
- STAN5
- MIXH
- JWSPL
- JWDPL
- JIMPS
- SKEW T (Version I & II)

5.1 MOD3A

The HP 9820 breadboard version of the REED Description, Model 3, previously used to monitor launches (46-49) has been rewritten, liberally commented, and made research operational on the REEDA System as an interactive program to test human factors and provide a real-time research capability for surface air quality predictions. The program asks questions of the user and accepts answers in English words and phrases. Using an X-Y plotter, it draws concentration and dosage versus distance plots as well as isopleth contour plots. The equations used for the cloud rise and diffusion are in an extremely simplified form and are being expanded to give a more accurate representation of the cloud mechanics and the diffusion process. This version does not permit diffusion calculations aloft, does not allow for options like surface absorption, rain scavenging, or $\text{Al}_2\text{O}_3$ deposition.

*These have been merged into the NASA/MSFC REED Diffusion Model Program Version I.
The distinct advantages of having the diffusion model operational on the REEDA System are two-fold. First, because the system is dedicated, the program can be run in almost real-time, thereby allowing last minute analysis and decisions to be made. Secondly, because of the interactive nature of the program, it is not necessary to have a trained computer person run it. Any scientific person knowledgable in diffusion theory can, with a brief orientation, successfully operate the program. Knowledge of diffusion theory is required because SIGAR and the top of the transport layer determination calculations have not yet been automated.

5.2 MOD3B

A version of MOD3A, called MOD3B, has been written for the REEDA System to use the Plasmascope installed on the system. Because of the Touch Panel feature on the scope, it is easier for the user to answer the yes/no type questions asked by the program. He need only touch the YES or NO area on the screen instead of typing in the answer. Further man-machine interface improvements using the Plasmascope are planned for MOD3B to make the program, both input and output, as simple and informative as possible.

5.3 JIMPL

A program, written in FORTRAN, to process the Jimsphere wind data was created on the REEDA System. This program produces both scalar wind speed and wind direction plots. An example of each is given in Figure 5-1 and Figure 5-2 respectively. This program requires as input the following data on altitudes ranging from 25 to 20,000 meters.

- Time
- Date
- Altitude
- Wind Direction
- Scalar Wind Speed
Figure 5-1. Example Jimsphere Scalar Wind Speed Plot
Figure 5-2. Example Jimsphere Wind Direction Plot
This program was used to initially process the KSC and Point Mugu Jimsphere wind data to determine temporal variation in the atmospheric kinematics to support climatic diffusion assessments. Over 150 plots were generated. Several modifications were found desirable such as the inclusion of a filter to eliminate bad data or noise, and provide the ability for the user to select only those specific profiles of interest. The ultimate desire was to be able to see a plotted profile without having to actually plot it. This would allow the user to process only data of interest and allows the creation of final Jimsphere profile plots without having to process the data several times.

Consequently, programs to process Jimsphere wind speed/direction (JWSPL, JWDPL and JIMPS) were developed for the REEDA Plasmascope which allows for "touch panel" control. Research or production options are available to allow the user to process all, or portions, of the data with graphic plots on the Plasmascope or hard copy plots. Program JIMPS allows the user to visually display a complete Jimsphere wind speed direction plot on the Plasmascope, thus allowing the user to quickly scan and edit the data before making a hard copy plot. This feature ensures the ability to only generate useful hard copy plots.

The programs JWSPL and JWDPL process the Jimsphere Wind Speed/Direction data respectively. Each allows the user to easily process Jimsphere data quickly through "touch panel" questions and answers, thus eliminating the possibility of erroneous keyboard input. An example scenario from the program JWSPL is given in Figure 5-3. Hopefully, it can be seen from the scenario that by using the Plasmascope "touch panel" control the possibility of making input errors (keyboard) are reduced. A noncomputer oriented user can easily be taught to use such a program within minutes.

Figure 5-3. Example of Operating JWSPL Plasmascope Program
The overall results of the Plasmascope Jimsphere programs have been quite successful and time saving. Over 700 finalized Wind Speed and Wind Direction profiles have been generated from the KSC and Point Mugu data.

5.4 METPL

METPL is currently a stand alone research program generated to allow visual display of Wind Speed, Wind Direction, Dry Temperature, Potential Temperature, and Cloud Stabilization Height as one profile upon the Plasmascope. This program should be interfaced to MOD3B. As an example of the meteorological profile as it appears on the Plasmascope is shown in Figure 5-4. Various questions will appear at the bottom of the Plasmascope to direct the user as to the moving up or down of the top of the surface mixing layer to the desired height as well as giving the option for a hard copy plot of the generated profile. The meteorological profile is normally obtained from a Rawinsonde of the atmosphere. To obtain the entropy profile required for these soundings, the temperature and pressure are translated into the potential temperature in accordance with the following equation:

\[ \theta = T \left( \frac{1000}{p} \right)^{0.288} \]

where the concept of a potential temperature (\( \theta \)) is introduced to reference the temperature to a specific pressure (1000 mb).

5.5 STAN5

Program STAN5 is a research stand alone program written in FORTRAN and operates on the REEDA System. This program should be interfaced to the MOD3B program. STAN5 calculates the standard deviation of the horizontal wind azimuth angle, SIGAR. Input data are the temperatures, pressures, and altitudes of the first three data levels of KSC Rawinsonde soundings. The levels are the first and second standard
Figure 5-4. Example of METPL Plasmroscope Program
altitude levels (16 and 1,000 feet) and the first mandatory pressure level (1,000 mb). The roughness length along the air trajectory with the surface transport layer is also an input variable. The background for the calculation is described in Section 2.

The output of STAN5 includes the time and date of the Rawinsonde sounding, the input data, calculated non-dimensional parameters, the gradient of potential temperature, and SIGAR.

5.6 MIXH PROGRAM

Program MIXH is a stand alone research program which operates on the REEDA system. MIXH selects a surface transport layer height based on criteria described in Chapter 2. The input data is a Rawinsonde sounding. MIXH calculates virtual temperature at each level and tests the data according to the prescribed criteria for virtual temperature gradient corresponding to the base of a stable layer and the top of a stable layer. The layers must have a thickness of at least 100 meters. The base of the stable layer nearest to the ground is offered as the height of the surface transport layer. If a stable layer is ground based, then the top of the stable layer is selected as the transport layer height. If no stable layers are found between the surface and 3000 meters, then the transport layer height is set equal to 3000 meters. The output of MIXH is the mixing height of the surface transport layer. If the theory is upheld by extensive test, it should be interfaced to the MOD3B program.
5.7 SKEW T

The existing SKEW T REEDA System program, originally written by Dr. J. B. Stephens of MSFC, was modified to enhance its capabilities in processing sounding data. It can currently accept sounding data from both magnetic tape or disc and in a variety of user specified formats. The SKEW T program generates logarithmic plots for both dew point and temperature as a function of altitude as shown in Figure 5-5.

The SKEW T program was used to process some 23 cases of Battelle Thiokol data for 1974. One additional modification was made to the SKEW T program to allow for processing the Battelle data, which was the calculation of dew point from a given relative humidity and temperature.

5.8 CONCLUSIONS AND RECOMMENDATIONS

These conclusions and recommendations are drawn from the discussion of the interactive REEDA software described in Section 5-1 thru 5-7. It should be evident that a variety of sophisticated interactive REEDA software has been generated and utilized during this contractual period. A vast amount of data from various sources have been processed, analyzed, plotted, etc., by the different REEDA programs. The REEDA software has proven effective, efficient, and invaluable in providing both fast/accurate results in both statistical and graphical form. The current REEDA software, especially the Plasmascope programs provide a means for even a non-computer oriented user to operate and get results with very little effort. The Plasmascope "Touch Panel" capability provides not only for faster user response (i.e., touch-vs-keyboard) but proves superior to the CRT program due to the fact it virtually eliminates or safeguards the user from entering an erroneous value/answer. In addition, due to the 512 by 512 raster dot resolution provided by the Plasmascope virtually

5-10
Figure 5-5. Example of SKEW T Plot
unlimited visual graphic display can be generated.

It is recommended that all existing stand alone REEDA software be extensively tested and validated to its fullest extent, with state-of-the-art Plasmascope technology being incorporated whenever and wherever feasible. Additional REEDA software should also be developed, utilizing the REEDA Plasmascope technology, to provide even more capabilities in processing both present and future sources of data.
6. NUMERICAL CLOUD RISE MODEL

Under contract with the Army Missile Command High Energy Laser Programs Office, SAI has recently developed a digital computer program (PUFF) representing a first-order mathematical model for describing the behavior of clouds produced by short-duration high temperature exhausts. In order to more clearly identify and understand the important features associated with the problem of cloud behavior, the cloud history was divided into three phases as depicted in Figure 6-1 and as tabulated in Table 6-1. As indicated in the figure and table, the cloud's history from the time of its initial formation until it reaches equilibrium altitude is contained within Phases I and II. PUFF was primarily designed to handle the problem of cloud behavior during these two phases.

The basic model upon which PUFF is based is the result of a study of relevant literature, both theoretical and experimental. In essence, the cloud is treated as an open thermodynamic system within which all properties are assumed to be uniform. The cloud shape is represented by a sphere and cylinder combination as shown in Figure 6-2. The cloud behavior is predicted by the simultaneous numerical solution of the

- Conservation equations for
  1) Mass
  2) Momentum (3 components)
  3) Energy
- Equation of state
- Volume and center of mass relations for cylinder and sphere combinations.

- Temperature
- Density
- Shape\(^*\)

### 6.1 MODIFICATIONS TO PUFF

Some modifications to PUFF are necessary to allow it to be applied to the situation shown in Figure 6-3. Some of the changes are general, relating to both the duct cloud and the ground cloud, while other changes deal with the ground cloud only.

#### 6.1.1 General Changes

General changes to the program include:

1. The introduction of atmospheric density and temperature profiles,
2. The calculation of energy released by chemical reaction,
3. The calculation of thermal radiation emitted by the exhaust products and
4. The calculation of the behavior of liquid droplets and solid particulates suspended in the exhaust gases.

The use of atmospheric density and temperature profiles would be based on atmospheric data obtained from soundings. Soundings are taken at regular time intervals before each firing and twice a day normally.

The calculations of the energy released by chemical reaction would involve maintaining an inventory of the chemical species present in the cloud and computing the rate and total amount of each significant reaction associated with the production or consumption of each species. The techniques used in the afterburning analysis and for maintaining an inventory of chemical species have been discussed in Section 3.2.

\(^*\)In terms of length of cylindrical tail and radius of spherical body.
Figure 6-3. Exhaust Cloud Configurations
The spectral characteristics of the thermal radiation emitted by the exhaust products (gaseous, liquid droplets, and solid particulates) are quite complex and calculation of such characteristics is not a simple task. The total radiation emitted by the various constituents, however, can be calculated by standard engineering techniques and should prove adequate for the type of model under consideration.

The behavior of liquid droplets and/or solid particulates within the cloud depends upon the size of the droplets/particles and the velocity of the flow. Methods for predicting such two-phase flow phenomena have been presented in Subsections 3.1 and 3.3.

6.1.2 Ground Cloud Changes

In addition to the four general changes noted in the preceding subsection, there are certain modifications which relate specifically to the ground cloud alone. PUFF was not originally designed for the case where the rocket exhaust impinges on a solid surface. The program can be easily modified such that in the presence of a solid surface, a surface force is introduced into the momentum equations in such a way that the ground cloud center-of-mass cannot pass through the surface.

Although the ground cloud center-of-mass does not penetrate the surface, allowance must be made for mass, momentum, energy, and species to escape from the ground cloud through the flame trench entrance and ultimately into the duct cloud. All such losses to the ground cloud would be added to the duct cloud to satisfy basic conservation principles. Calculations of the magnitude of the losses would depend upon the height of the rocket engines above the flame trench entrance. As the launch vehicle ascends, the amount of exhaust gases passing through flame trench entrance decreases. This decrease results from the vertical rocket
exhaust plume cross section (at ground level) increasing with time while the velocity within the plume (as ground level) is decreasing.

In the original version of PUFF, the origin of the coordinate system was the center of the jet exit plane. For the case of the ground cloud, this origin would move upward as the launch vehicle ascends. Because it is desirable to have an origin which is stationary with respect to the ground level, PUFF must be modified such that the origin remains fixed at a point corresponding to the center of the rocket exhaust exit plane prior to liftoff. The rocket exhaust exit plane after liftoff will be programmed to move upward in accordance with the known trajectory of the launch vehicle.

Another modification to the program would involve the manner in which the buoyant force is calculated for the ground cloud. Currently in PUFF the buoyant force depends on the difference between the mean cloud density and the atmospheric density at ground level. The atmospheric density surrounding the tail of the ground cloud varies with altitude and thus the buoyant force should involve an integral of the density difference over the altitude interval from ground level to the end (top) of the ground cloud tail.

6.2 CURRENT STATUS OF PUFF PROGRAM

The PUFF Program was converted from the IBM 370 to execute on the REEDA System. Various software incompatibilities had to be resolved, such as:

- Label common not supported
- Multiple entry points not supported
- Initialization of common variables in data statements not supported
- Block data not supported
- Namelist read not supported

6-8
These were the initial problems which had to be resolved for a successful compilation. A benchmark run for PUFF on the REEDA System has been established. The necessary logic has been prepared to modify PUFF to account for:

- a variable atmosphere
- a moving exhaust nozzle
- a solid ground level

A mathematical model for calculating the jet stagnation length has been established. The necessary data for calculating the radiative emittance of the exhaust products have been collected. Once this was accomplished a benchmark comparison was made; however, some discrepancies were noted. When the REEDA version of PUFF was compared to an IBM 370 operational version identical results were obtained from the initial time until time was equal to 0.10 seconds using 0.01 sec time increments. At this point in the execution of the program, the time increment was increased to 0.10 second. Using the new time increment, significant differences begin to appear in the calculated results. Various modifications were made to try to eliminate the difference. All variables and calculations were changed to double precision. Various complex arithmetic computations were re-structured into less compound statements to eliminate possible loss of accuracy by truncation, etc. The above changes have not affected the final results. There still remained differences in the results when the time increment was increased to 0.10 second. Thus it was decided not to increase the time increment, but to leave it constant at .01 second for the entire duration of the program to determine if better accuracy is gained at larger times into the run; however, the results did not change. Consequently, analysis of the REEDA version of the PUFF Program will continue with appropriate modifications being made.
It should be noted, however, that due to the difference in hardware (i.e., IBM 370 vs HP 21MX REEDA), 32 bit vs 16 bit single precision words), 64 bit double precision vs 48 bit double precision words), (16 significant digits vs 11 significant digits), complete agreement between the results of the two machines may not be obtainable given the algorithms that exist currently in the PUFF Program.

6.3 CONCLUSIONS

A new numerical cloud rise program developed for another purpose has been investigated to see if it is suitable for use on the exhaust cloud from the Space Shuttle propulsion system. Development has been initiated to modify the original code and convert it for use on the REEDA system. The use of this code would allow the simultaneous determination of the cloud shape and size and the radiation loss from the exhaust effluents. No other known analyses can handle the situation as aptly as the PUFF code.
7. OVERALL CONCLUSIONS AND RECOMMENDATIONS

The study performed under NASA Contract NAS8-31806 has yielded large dividends in the technology learned, the basic algorithms developed, the meteorological knowledge about KSC brought to a useful form, and the large amount of software developed. New techniques utilizing the touch panel on the Plasmascope have yielded programs that are convenient and rapid to use. The effort has basically completed the necessary homework for a full scale climatological diffusion assessment; what is now required is to bring together the various models and start the development of an operational diffusion model useful not only for a climatological assessment but for monitoring operational launches. The technique for the calculation of the SRB exhaust effluents has been developed but so far losses due to plume impingement, radiation, the flame trench, and water injection have not been considered. A preliminary climatological diffusion assessment was performed to validate the techniques developed; the results have only limited validity and no conclusions can be drawn from the results of the study. The study assumed the Space Shuttle was a Titan type vehicle with only solid propellant boosters; the liquid propellant SSME and their interactions with the solid motor effluents were not considered.

7.1 RECOMMENDED STUDY

Ground-based stable layers and inversions are common over land areas near KSC during calm clear nights, especially in winter. The percent frequency of occurrence of ground based inversions for various thickness intervals by season at KSC (50) is given in Table 7-1.
Table 7-1. Percent frequency of occurrence of ground-based inversions by season at KSC during 1965 - 1969 at 0700 and 1900 EST.

</tbody>
</table>
The statistics in Table 7-1 are based on Rawinsonde data. Shallow ground based inversions (thickness less than 250 m) reported at KSC are based on a surface temperature (at 16 ft) and a temperature at the first mandatory pressure level (1,000 mb). Since the temperature at 16 ft is strongly influenced by local micrometeorological conditions the statistics of shallow inversions are not representative of other locations beyond a short distance from the measurement location. However if inversions are reported based on temperature observations at three or more altitudes (including the observation at 16 ft) there is more support for the argument that stable conditions exist near the ground over a wider area in the vicinity of the measurement site. Since a ground based stable layer at a particular location will effectively insulate that location from the stabilized SRB cloud, it is important to establish the applicability of the available KSC inversion statistics to the climatological impact analysis. The physical processes responsible for the formation of ground-based inversions in the areas surrounding KSC are influenced by the relative distribution of rural and urban topography and water bodies. Urban areas and water bodies during winters at KSC represent nocturnal heat sources which could contribute to the maintenance of a nocturnal mixed layer. Although a nocturnal mixed layer has been identified over large cities (51, 52) its existence has not been identified or correlated with nocturnal heat sources in the vicinity of KSC.

It is a reasonable hypothesis that the inversion statistics obtained from KSC Rawinsonde data are not necessarily representative of conditions at all locations of interest in the vicinity of KSC. It is suggested than an experimental study be implemented to establish the relative strength and frequency of occurrence of ground based stable layers and inversions over various locations of interest near KSC. Adequate results would be obtained by sampling
temperatures aloft (to 1 km) daily, 1 hour before sunrise, during January and February over population centers (Titusville, Cocoa), working areas, and viewing areas within KSC boundaries. The purpose of the study will be the establishment of the degree of conservatism of air quality impact calculations based on the available large sample of Rawinsonde data at KSC.

**UNDEFINED SYMBOLS:**

A-11
HP 2100 EBCDIC → ASCII Conversion Programs
ASMB.R.L.F

THIS SUBROUTINE CONVERTS REAL NUMBERS IN IBM FORMAT TO HP FORMAT

WHERE: IBN1 - THE MOST SIGNIFICANT PART OF THE IBM REAL WORD

IBN2 - THE LEAST SIGNIFICANT PART OF THE IBM REAL WORD

HP - THE REAL WORD IN WHICH THE RESULT IS TO BE STORED

MAN IBMHP

ENTRY/EXIT POINT

GET ADDRESSES OF PARAMETERS INTO

IBN1 IBM1, IBM2, AND HP1

IBN2 IBM1, IBM2, AND HP1

HP1 IBM1, IBM2, AND HP1

IBMHP. HP

LDI HP1

SET UP THE ADDRESS OF THE SECOND

HALF OF THE HP REAL WORD

LDA HP2

GET FIRST PART OF IBM REAL WORD

AND =B077406

MASK OFF THE EXPONENT

ALF ALF

SHIFT TO LOWER 8 BITS OF A

ADA IBIAS

REMOVE IBM EXPONENT BIAS OF 64

ADA A

QUADRUPLE EXPONENT TO MAKE IT

ADA A

A POWER OF 2

SSA

SKIP IF POSITIVE EXPONENT

JMP NEGEX

JUMP IF NEGATIVE EXPONENT

ALR

POSITIVE EXPONENT -- ROTATE IT

JMP STEX

1 BIT RIGHT AND STORE

NEGEX RAL

NEGATIVE EXPONENT -- SHIFT IT 1

AND =B000376

MASK OFF JUST THE EXPONENT

SZA

SKIP IF EXACTLY ZERO

IOR =B000001

PUT IN SIGN BIT

STEX STA TEMP

STORE THE EXPONENT TEMPORARILY

LDA IBN1, I

GET FIRST PART OF IBM REAL WORD

RAL

ROTATE IT LEFT 1 BIT

AND =B000001

MASK OFF MANITSSA SIGN BIT

STA B

STORE IN B REGISTER

LDA IBN2, I

GET SECOND PART OF IBM REAL WORD

ARS

DROP LEAST SIGNIFICANT BIT OF MANITSSA

AND =B077777

AND CLEAR THE UPPER BIT

S28, R85

SKIP IF MANITSSA IS NEGATIVE

JMP +2

DON'T COMPLEMENT IF MANITSSA POSITIVE

CMA, IN8

MANITSSA NEGATIVE, COMPLEMENT

AND =B000377

GET LOWEST EIGHT BITS

ALF ALF

PUT IN UPPER PART OF WORD

IOR TEMP

OR IN THE EXPONENT

STA HP2, I

PUT IN SECOND HALF OF HP REAL WORD

This report documents results of a study which had as its primary objective the development of techniques to determine the environmental effects from the Space Shuttle SRB exhaust effluents. The study developed many new and needed tools which were used to perform a preliminary climatological assessment. This preliminary study will be used to guide the future full-scale climatological assessment. The exhaust effluent chemistry study was performed and, neglecting several possibly important effects, the exhaust effluent species determined. A reasonable exhaust particle size distribution has been constructed for use in future nozzle analyses and for the deposition model. The effects of scavenging and absorption were not included in the preliminary assessment. The preliminary assessment was used to identify problems that may be associated with the full-scale assessment; therefore, these preliminary air quality results should be used with caution in drawing conclusions regarding the environmental effects of the Space Shuttle exhaust effluents.
