ABSTRACT

An aeroelastic investigation of horizontal axis wind turbines is described. The study is divided into two simpler areas, namely, the aeroelastic stability of a single blade on a rigid tower, and the mechanical vibrations of the rotor system on a flexible tower. Some resulting instabilities and forced vibration behavior are described.

INTRODUCTION

The aeroelastic analysis of horizontal axis wind turbines may be divided into two convenient areas, namely, (a) the investigation of the aeroelastic stability and response of a single blade on a rigid tower, and (b) the investigation of the mechanical stability and vibrations of the rotor system on a flexible tower. With a reasonable understanding of the behavior in these two areas, the more complex problem involving a completely coupled blade-tower aeroelastic system can be better understood.

The present report deals with some work performed for ERDA in the two areas cited above. The aim has been to investigate the basic mechanisms and to reduce these analyses to forms in which they can be readily used for trade-off analyses.

AEROELASTIC STABILITY OF SINGLE BLADE

Using the equivalent hinge concept, the nonlinear equations of motion were written for large deflections of a rigid blade, with elastic hinges at the root, rotating about a rigid tower. The blade was assumed to have a flapping ($\beta$), lagging ($\phi$), and feathering ($\theta$) degree of freedom, and the effects of preconing of the blade relative to the feathering hinge ($\delta$), and of the feathering hinge relative to the plane of rotation ($\beta_H$), were included. Quasi-steady aerodynamic forces were assumed. The equations were first solved to obtain the static, steady state displacement in flap ($\beta_0$) and lag ($\phi_0$). Then the equations of motion were linearized by assuming small perturbations about the steady state flap and lag displacements found above. The resulting linear equations take the form

$$[A] \{\ddot{x}\} + [D] \{\dot{x}\} + [K] \{x\} = 0$$

(1)
where \{x\} represents the perturbation displacements in \(\beta, \phi, \theta\) and 
\([A], [D], [K]\) represent the 3x3 mass, damping, and stiffness matrices 
respectively. These equations were investigated for stability by 
recasting them as standard first order equations, and extracting 
the eigenvalues \(p_n = a_n + i b_n\) using standard procedures. The 
resulting \(a_n\)'s indicate the damping characteristics, and the \(b_n\)'s 
the frequencies of the resulting oscillations.

A wide range of parametric variations are being investigated. 
Figure 1 shows some typical results from this analysis showing 
effects of preconing on the stability margins. The results are 
presented in the form of modal critical damping ratio \(\zeta \approx -\frac{a_n}{b_n}\) 
since it is believed this more clearly indicates the strength of the 
instability (or stability) than simple stability boundaries. It is 
seen here that positive droop angles (\(\delta\)) can particularly decrease 
the stability margin.

The analyses described above have been based on equivalent 
hinges in order to provide a rapid and reasonably accurate tool for 
predicting stability characteristics. However, a more elaborate 
program is being developed which allows for distributed flexibility 
of all three hinges, and this program will be used to validate the 
results using equivalent hinges.

The linear aeroelastic stability analyses have been supplement-
ed by some nonlinear, large deflection analyses again using equiva-
lent hinges, to determine the nonlinear limit cycle behavior of 
these instabilities. The harmonic balance method was applied and 
the resulting nonlinear equations were solved by the Newton-Raphson 
technique. Both the self-excited aeroelastic instabilities and the 
dynamic response to gravity and wind shear loads were investigated. 
Figure 2 shows the nonlinear limit cycle behavior of a predominantly 
flapping-torsion type instability as rotation speed \(\Omega\) is increased. 
The nonlinearity tends to be of a softening type, i.e., steady limit 
cycles can occur somewhat below the linear critical rotation speed 
if a large enough disturbance is given to the system.

MECHANICAL VIBRATIONS OF ROTOR-TOWER SYSTEM

The mechanical instabilities and vibrations that may result 
from the interaction of the flexible rotating blades with the base 
motions of the supporting tower were also investigated. The sim-
plest of these interactions involves the coupling of the tower side 
motions (\(q_L\)) with the blade lagging motions (\(\phi\)), which can give 
rise to a strong mechanical instability (the "ground resonance" effect 
of helicopters), as well as significant forced vibration effects 
due to blade unbalance and gravity forces. Using the equivalent 
hinge concept, the equations of motion for small vibrations of such 
a rotor-tower system are

\[
M_L \dddot{q}_L + c_L \dot{q}_L + k_L q_L + \sum_i S_i \frac{d^2}{dt^2}(\phi_i \cos \psi_i) = \Omega^2 \sum_i S_i \sin \psi_i
\]

\[
S_i \cos \psi_i \dddot{\phi}_i + I_i \dddot{\phi}_i + c_\phi \dot{\phi}_i + k_\phi \phi_i = g[S_i \sin \psi_i + S_i \phi_i \cos \psi_i]
\]

\(i = 1, 2, \ldots N\)
where \( \psi_i = \Omega t + 2\pi(i-1)/N \) represents the angular position of the \( i \)th blade, \( g \) is the acceleration of gravity, \( M_T \) is the equivalent tower mass of the tower and rotor, and \( S_i \) and \( I_i \) represent the static moment and moment of inertia of the \( i \)th blade about the lag hinge.

The mechanical stability of this rotor-tower system can be found by neglecting gravity and blade unbalance forces (\( g = 0, S_i = \text{const} \)), and introducing the multiblade coordinate transformation

\[
\phi_i = a(t) \sin \psi_i + b(t) \cos \psi_i
\]

This eliminates all the periodic coefficients in Eqs. (2) for \( N \geq 3 \), and the stability of the resulting equations in \( q_L, a, b \), can be investigated in the standard manner. Figure 3 shows the results for a typical 3-bladed rotor with varying amounts of critical damping ratio \( \zeta_i \) in the tower and in the blades. In general adding damping stabilizes the system, but under certain circumstances, the addition of unequal amounts of damping can destabilize the system from the no damping case. For a 2-bladed rotor, effects are similar, but with additional small instability regions.

Effects of small, static unbalance can be found by assuming that \( S_1 = S + \Delta S, S_2 = S_3 = \ldots = S \). The right hand side of Eqs. (2) then reduces to the forcing function \( \Omega^2 S \sin \Omega t \). By neglecting the small \( \Delta S \) variations in the periodic coefficients, and introducing again the multiblade coordinate transformation, Eq. (3), the basic equations reduce to the forced harmonic response of a conventional spring mass system involving the coordinates \( q_L, a, b \). The resulting tower and rotor responses become

\[
q_L(t) = q_{LS} \sin \Omega t + q_{LC} \cos \Omega t
\]

\[
\phi(t) = \frac{b + a_s}{2} + \frac{b_s + a_c}{-2} \sin 2\Omega t + \frac{b_c - a_s}{2} \cos 2\Omega t
\]

where \( a_s, a_c, b_s, b_c \) are the sine and cosine responses of the coordinates, \( a, b \). Figure 4 shows the amplitude of the blade lagging response \( \phi \) for a typical case. It is seen that strong 2/rev resonance responses occur in the blade when the rotation speed \( \Omega \) equals 1/2 the lagging natural frequency \( \omega_\phi \) or when \( \Omega \) equals the tower natural frequency \( \omega_L \). Adding damping to the blade or to the tower reduces the respective amplitude accordingly.

The effects of gravity loading can similarly be investigated by examining Eqs. (2). Generally, gravity acts directly on each blade without much tower interaction. Strong 1/rev resonances may occur when \( \Omega \) equals the lagging frequency \( \omega_\phi \) and weak 0.5/rev parametric resonances may possibly occur when \( \Omega \) equals twice \( \omega_\phi \).

More comprehensive rotor-tower interactions were investigated by including the tower yawing motions (\( \theta_w \)) and the blade flapping motions (\( \delta \)) in the previous analyses. The mechanical instability regions occurred at slightly lower rotation speeds \( \Omega \) than before, but the general mechanisms were not changed significantly. These additional degrees of freedom.
also affected somewhat the static unbalance loads. Of more sig-
nificance was the direct effect of wind shear and tower shadow on the
blade flapping loads when these additional motions were introduced.
The investigation of these mechanical vibrations are continuing.

DISCUSSION

Q. Comment: It is the flywheel resonance and mechanical insta-
   bility problems that have primarily dictated natural fre-
   quencies of the tower well above the operating range of the
   rotor.

A. Yes. These factors play important roles, together with the
   forced vibrations due to rotor static unbalance, gravity
   loads, and air loads. Generally, I believe, to avoid signi-
   ficant "ground resonance" type mechanical instability, the
   blade lagging frequency (in-plane vibrations) would need to
   be above the rotation speed of the rotor. Low natural
   frequencies of the tower usually give rise to large forced
   vibration as the rotor speed passes through the tower natural
   frequency (and also through one half the tower natural
   frequency for two bladed rotors).
