The radar backscatter from the sea depends upon both the magnitude and direction of the wind vector. This dependence can be explained by both theoretical and empirical models. These results are extremely important since in the near future NASA proposes to launch the SeaSat-A oceanographic satellite. One of the goals of this satellite is to demonstrate the feasibility of global wind speed and direction measurements over the ocean. Such wind vector information will provide meteorologists with essential input into wave and weather forecast models.

Several regression models are proposed to explain the wind direction dependence of the 1975 JONSWAP (Joint North Sea Wave Project) scatterometer data, in which continuous directional observations were made by flying in a circle. The models consider the radar backscatter as a harmonic function of wind direction. The constant term accounts for the major effect of wind speed and the sinusoidal terms for the effects of direction. The fundamental accounts for the difference in upwind and downwind returns, while the second harmonic explains the upwind-crosswind difference. Possible higher order effects would appear as coefficients of the higher harmonics. The first model considers only terms involving the fundamental and second harmonic. The second and third models are more general, since third and fourth harmonics are included, respectively.

The results, for angles of incidence of 40° and 65°, indicate that third order effects are negligible. Also, for all cases, the first model, which used only cosine terms up through the second harmonic, appears to explain the angular variation adequately. The coefficients of this model are related to the wind speed by a power-law expression. The relationship is extremely valuable, since it simplifies the process needed to determine a wind direction from two orthogonal scatterometer measurements. Thus, the results are of value to future satellite observations of the ocean.
An inversion technique is also proposed which will eliminate the effects of wind speed and direction. This approach assumes that two orthogonal scattering measurements are available. Also, if swell or the large-scale waves do not line up with the wind waves, it is assumed that the necessary information is available to correct for these effects. The technique performs adequately under these constraints, and also, when possible higher order wave effects are present.

A comparison between two different types of sea scatter theories, one type represented by the work of Wright and the other by that of Chan and Fung, was made with recent scatterometer measurements. Wright's theoretical model differs from that of Chan and Fung in two major aspects: (1) Wright uses Phillips' model for the sea spectrum, while Chan and Fung use Mitsuyasu and Honda's spectrum as proposed by Pierson; (2) Wright uses the modified slick-sea slope distribution of Cox and Munk defined with respect to the horizon, while Chan and Fung use Cox and Munk's slick-sea slope distribution defined with respect to the plane perpendicular to the look direction.

Satisfactory agreement between theory and experimental data were obtained when Chan and Fung's model was used to explain the wind and azimuthal variation of the radar backscatter. Wright's theory does not include anisotropic characteristics, and hence, can be only used to show wind speed and incidence angle dependence. Since Phillip's sea spectrum is independent of wind speed, Wright's model does not show significant wind dependence, and thus, leads to poorer agreements with experimental data.
2.0 AN EMPIRICAL MODEL FOR OCEAN RADAR BACKSCATTER AND ITS APPLICATION
IN INVERSION ROUTINE TO ELIMINATE WIND SPEED AND DIRECTION EFFECTS

A. Modelling the Wind Speed Dependence of Sea Return

The ocean surface can be viewed simplistically as consisting of
waves of two scales: (i) gravity waves which have wavelengths much
longer than those of the radar, and (ii) capillary waves which have
wavelengths on the order of or smaller than the radar wavelength. At
microwave frequencies and for incidence angles in the range 80° > \( \theta > 25° \),
the radar return, especially the vertically polarized case, can be ade-
quately explained in terms of the first order Bragg scattering theory.
The selected ocean wavelength predicted by this theory is related to
the radar wavelength by

\[ \Lambda \sin \theta = \frac{\lambda}{2} \]  

(2-1)

where \( \Lambda \) = ocean wavelength
\( \lambda \) = radar wavelength

Thus, a strong dependence of the radar return upon the sea spectrum in
the capillary region is expected. Pierson (1975), Mitsuyasu and Honda
(1974), and others have shown that the sea spectrum in the capillary
region grows with increasing wind speed. For this reason, a strong
correlation between radar sea return and the wind speed over the sea
surface is anticipated.

Work by many experimenters, most recently Young and Moore (1976),
and Jones, Schroeder, and Mitchell (1977) suggest that the wind speed
can be determined from the radar backscatter by using an empirical rela-
tion of the form:

\[ \sigma^o = A U^Y \]  

(2-2a)

or

\[ \sigma_{dB} = A_{dB} + Y (10 \log U) \]  

(2-2b)
where $A$ = levelling constant
$U$ = wind speed
$\gamma$ = wind speed power coefficient.

The effect of wind direction on sea returns has not been as extensively explored as the magnitude dependence. The majority of research in this area has been conducted under the NASA AAFE (Advanced Aircraft Flight Experiment) program. Attempts at modelling this effect, however, have never been truly satisfactory, since a relationship between the coefficients of the models and wind speed has not been shown previously (Afarani (1975)).

Several regression models were applied to the 1975 JONSNAP (Joint North Sea Wave Project) circle-flight data in an attempt to determine the wind direction and speed dependence of the radar returns. The proposed models assume the backscatter to be a harmonic function of wind direction. The constant term accounts for the major effects of the wind-speed magnitude and the sinusoidal terms account for the effects of wind direction. The fundamental accounts for the difference in the upwind and downwind returns, while the second harmonic explains the upwind-crosswind difference. Possible higher order effects which may occur are accounted for in some of the models by the higher order harmonics. To include these possibilities the following regression models were proposed.

Model 1: \[
\sigma^0(U, \theta, \phi) = \sum_{n=0}^{2} A_n(U, \theta) \cos \left[n(\phi-\phi_u)\right] \tag{2-3a}
\]

Model 2: \[
\sigma^0(U, \theta, \phi) = \sum_{n=0}^{3} A_n(U, \theta) \cos \left[n(\phi-\phi_u)\right] \tag{2-3b}
\]

Model 3: \[
\sigma^0(U, \theta, \phi) = \sum_{n=0}^{4} A_n(U, \theta) \cos \left[n(\phi-\phi_u)\right] \tag{2-3c}
\]

where $A_n(U, \theta) =$ coefficient to be determined through regression
$\phi =$ measurement direction from North, in degrees
$\phi_u =$ upwind direction, in degrees
$U =$ wind speed, m/s
$\theta =$ incidence angle (relative to vertical)

(Jones, Schroeder, Mitchell, 1978)
The multiple correlation coefficient, $R^2$, was chosen to provide a numerical evaluation of the regression analysis. $R^2$ is a measure of the "proportion of total variation about the mean explained by the regression;" a perfect fit has a value of one (Draper and Smith, 1966).

By fitting Model 3 to the measured data, values for the $A_n$'s are obtained as shown in Table 1. These $A_n$'s are for a given incidence angle, $\theta$, and a given flight (or wind speed). Reasonable improvements in the $R^2$ value due to use of third and/or fourth harmonics would imply that higher order effects are significant. As Table 1 shows, this is not the case. Even flight 16, which has unequal crosswind values, appears to be adequately explained by Model 1, as shown in Figure 1.

Since the second-harmonic model adequately explains the wind direction effects on backscatter, an attempt was made to determine a relationship between the three regression coefficients of this model and wind speed. The scattering coefficient is known to have a power-law dependence on the wind speed. A power-law relation of the following form is assumed for the $A_n$'s,

$$A_n(U,\theta) = \rho_n(\theta) U^{\gamma_n(\theta)}$$

(2-4)

where $\rho_n(\theta) =$ levelling coefficient

$\gamma_n(\theta) =$ wind speed power coefficient

This expression is fitted to the $A_n$'s shown in Table 1 at a given incidence angle. Figure 2 is an illustration of this case when $\theta = 40^\circ$. It is clear from Figure 2 that the assumed expression for $A_n$ does provide satisfactory fits, with the possible exception of $A_1$(WV). Table 2 shows the coefficients in (4) obtained through regression analysis for $\theta = 40^\circ$(Figure 2). This relationship is also shown using both AAFe and JONSWAP results in Appendix B.

B. WINDVEC - A Simple Inversion Technique to Eliminate Wind Speed and Direction Effects from Seasat Orthogonal Radar Backscatter Measurements

In the near future (1978), NASA intends to launch the Seasat-A oceanographic satellite, carrying as one of its instruments the Seasat Active Scatterometer System (SASS). The SASS will use four antennas

</table>
squinted 45° off the satellite subtrack to achieve "a star-like illumination on the earth's surface," Grantham, et al. (1975). An operational frequency of 14.6 GHz was chosen to provide maximum wind sensitivity and minimal atmospheric absorption. Both vertical and horizontal like-polarization measurements will be made over an incidence angle range of [25°, 55°]. Doppler filtering will be used to divide this 1000 km. swath into either 25 km. or 50 km. cells as specified by the SeaSat User Working Group (UWG).

The User Working Group has also specified that the SASS should be capable of measuring wind velocity within an accuracy of ±2 m/s (U < 20 m/s) or ±10% (U > 20 m/s) for wind speed, and an accuracy for wind direction of ±20°. This creates the need for an inversion technique, which will use the orthogonal measurements, to infer these quantities. This problem can be solved in two steps: (1) wind speed, and (2) wind direction.

1. Wind Speed

The wind speed can be estimated within the user's requirements by using the average for the same point from orthogonal viewing angles. This average is approximately equal to the radar cross section when the aspect angle is 45°, i.e.

\[
\sigma^0(\phi = 45°) = \frac{\sigma_{1}(\phi_1) + \sigma_{2}(\phi_1 + 90°)}{2}
\]  

(2-5)

From Model 1, it can be shown that (5) becomes exact for \( \phi_1 = -45° \) and it provides the worst estimate when \( \phi_1 = 135° \). This is true for any incidence angle for which Model 1 is valid. It should also be noted that (5) provides poorer estimates when the upwind-downwind ratio becomes larger.

As an illustration, the relationship between \( \sigma^0(\phi = 45°) \) and wind speed is shown in Figure 3 for \( \theta = 40° \). Again a power-law dependence of the form

\[
\sigma^0(\phi = 45°) = a_1(\theta)U_1(\theta)
\]

(2-6)
Figure 3: Wind speed power-law dependence of the radar cross section at $\phi = 45^\circ$. 
provides satisfactory fits to the data. Consequently, the wind speed can be estimated knowing the average of the two scatterometer measurements, i.e.

\[ \hat{U} = \left[ a \sigma_{AV}^2 \right]^\gamma \]  

(2-7)

where \( a = 1/a_1 \): \( a_{(HH)} = 85.1, a_{(VV)} = 60.0 \)
\( \gamma = 1/\gamma_1 \): \( \gamma_{(HH)} = 0.47, \gamma_{(VV)} = 0.45 \)

As a test, wind speed errors were obtained from scattering coefficients calculated using the wind direction models. As seen from the results in Figure 4, the wind speed error can be expressed by

\[ U_{err} = C_0 + C_1 \cos(\phi + 45^\circ). \]

A wind speed correction of this form would offer considerable improvement if the data set had no fading or other random fluctuations. However, the SASS measurements will include fading and instrument bias.

At present, no wind speed correction is employed. When this technique is applied to orthogonal pairs of JONSWAP measurements the results are still within the UWG's guideline of ±2 m/s (\( u \leq 20 \text{ m/s} \)) or ±10% (\( u > 20 \text{ m/s} \)).

As an illustration, the wind speed errors for flight 17 are shown in Figure 5. Appendix C shows the wind speed error for the remaining JONSWAP flights.

2. Wind Direction

In the previous section, it was shown that the wind direction effects on \( \sigma^0 \) can be modelled by expression (3a). The regression coefficients of (3a) have a wind speed dependence given by Equation (4). In Section A, a method was discussed for determining an estimate of the wind speed, \( \hat{U} \). Using this estimate of wind speed, the scattering measurement can be modelled by

\[ \sigma^0 = \hat{A}_2 \cos 2\phi_w + \hat{A}_1 \cos \phi_w + \hat{A}_0 \]  

(2-8)

where \( \hat{A}_N \) are estimates obtained from (4) using the \( \hat{U} \) from (7).

Consequently, the wind direction, \( \phi_w \), can be found from

\[ \phi_w = \cos^{-1} \left\{ -\hat{A}_1 \pm \sqrt{\hat{A}_1^2 - \frac{8\hat{A}_2 (\hat{A}_0 - \hat{A}_2 - \sigma^0)}{4\hat{A}_2}} \right\} \]

Figure 5a: Wind speed errors vs U for flight 17, HH.
Figure 5b: Wind speed errors vs U for flight 17, VV.
Equation (9) holds for all incidence angles for which Model 1 is valid.

This inversion yields two estimated wind directions for each scatterometer measurement, one in the first quadrant and one in the second. These are mirrored to obtain estimates in the third and fourth quadrants, respectively. No information is known from the measurements themselves to determine the wind quadrant, but in an operational satellite system, such as SeaSat, this can be obtained from V-IR or conventional meteorological data.

Examples of the wind direction errors obtained when applying this technique to JONSWAP flight 17 are shown in Figure 6, where A and B are the fore and aft beam results, respectively. Considerable improvement can be obtained by averaging the results of both fore and aft measurements after they have been corrected to North. Results for flight 17 using this correction are shown in Figure 7. The wind direction errors produced by this method for vertical polarization are considerably lower than those for horizontal polarization, as seen by Table 3. One explanation for this observation is that the upwind-downwind scattering coefficient ratio increases with the wind speed much faster for the horizontally polarized case. Also, the scattering coefficient for the horizontal polarization can be much smaller than that for the vertical polarization and it drops off rapidly at large incidence angles. These later properties make it much more difficult to obtain reliable measurements.

C. Conclusion

The wind direction properties of radar backscatter were modelled by cosine fourier series through the fourth harmonic in wind direction from upwind. A comparison with JONSWAP data indicated that the effects of the third and fourth harmonic are negligible.

A simple inversion technique, which uses two orthogonal scattering measurements, is also shown which eliminates the effect of wind speed and direction. The procedure used is as follows:

1. Estimate wind speed from average $\sigma^0$ from 2 antennas
2. Estimate coefficients of directional equation by using $\sigma^0$ estimate from (1) and previously determined wind-speed dependence of coefficients.

(3) Estimate direction using coefficients from (2) and \(\sigma^0\) measured with antenna 1.

(4) Estimate direction using coefficients from (2) and \(\sigma^0\) measured with antenna 2.

(5) Average estimates of direction from (3) and (4) to produce new estimate of direction.

(6) Determine quadrant by comparing the 4 estimates of (5) with data from other sources such as:
   (A) concurrent satellite photos
   (B) meteorological analysis and forecasts based on observations at other times and places.

The results show that vertical-polarization is more effective in determining both wind speed and direction than horizontal-polarization.
3.0 COMPARISON OF SOME SCATTERING THEORIES WITH RECENT SCATTEROMETER MEASUREMENTS

A. Introduction

In recent years there has been general agreement that the scattering properties of the sea surface can be explained reasonably well in terms of a two-scale roughness model. It is understood in the two-scale model that the small waves are assumed to satisfy the small perturbation assumptions and that the large scale waves are to satisfy the Krichhoff approximation. This means that only certain high and low frequency portions of the entire sea spectrum are included as significant contributors to sea scatter. The basic approach is to use the first order result of the small perturbation method to compute the scattering coefficient due to small scale waves and to account for the tilting effect of the large scale waves by averaging this scattering coefficient over the slope distribution of the large scale waves. The tilting process not only produces an averaging effect but also causes depolarization of the incident electromagnetic field in the local reference frame leading to additional higher order terms (Fong, 1976). However, these higher order terms are unimportant when dealing with small sea slopes. As a result most authors ignore these higher order terms. It is known that the first order perturbation approach invariably produces a larger scattering coefficient for the vertical polarization than that for the horizontal polarization near grazing incidence. This fact remains unchanged after averaging. Since some recent near-grazing observations (Long, 1974) indicate that there are cases where the converse is true, special care must be exercised when applying such a theory to explain data at incident angles greater than 80°. As Wright (1968) pointed out, this type of theory is valid only in the mid-angular range approximately 30° to 80°.

Sea scatter theories using the two-scale model (Wright, 1968, Chan and Fung, 1977, Bass, et al., 1968, Wu and Fung, 1972, Long, 1974, Valenzuela, 1967) may be further categorized into two types: (a) those which use Phillips' (1966) sea spectrum together with a slope distribution of the
large scale waves defined with respect to the horizontal plane, and (b) those which use a growing sea spectrum (Pierson, 1975, Mutuyasu and Honda, 1974, Sutherland, 1967) and a slope distribution of the large scale waves defined with respect to the plane normal to the look direction. In the next section we shall briefly describe these two types of theory following Wright for type (a) and Chan and Fung for type (b). The predictions of these theories are compared with experimental observations in Section C and conclusions are given in Section D.

B. The Two-Types of Two-Scale Models

Wright's Sea Model. Many authors (Wright, 1968, Chan and Fung, 1977 and Valenzuela, 1967) have shown that for a slightly rough surface which satisfies the small perturbation assumption, the backscattering coefficient is given by

$$\sigma_{pp}(\theta, \phi) = 8k^4 \sigma^2 |\alpha_{pp}|^2 W(\theta, \phi)$$  \hspace{1cm} (3-1)

where for horizontal polarization, \( p = h \) and

$$\alpha_{hh} = \cos^2 \theta R_h$$

\( R_h \) is the Fresnel reflection coefficient for horizontal polarization defined in terms of the electric field. For vertical polarization, \( p = v \) and

$$\alpha_{vv} = R_v \cos^2 \theta + (k'^2 - k^2) T_v^2 \sin^2 \theta / (2k'^2)$$

where \( R_v \) and \( T_v \) are the Fresnel reflection and transmission coefficients defined in terms of the magnetic field for vertical polarization. In \( \alpha_{pp} \), \( k \) is the wave number in air; \( k' \) is the wave number in sea water and \( \theta \) is the angle of incidence. \( W(\theta, \phi) \) is the normalized anisotropic sea spectrum and \( \sigma^2 \) is the variance of the small scale sea waves. To include the tilting effect of the large scale waves, \(|\alpha_{pp}|^2 \) should first be modified by including higher order correction terms due to tilting and then (3-1) is averaged with respect to the slope distribution functions of the large
scale waves recognizing that \( \theta \) in (3-1) is to be replaced by the local incidence angle, \( \theta' \), which is a function of the local slopes. Wright indicated that satisfactory approximation could be achieved by assuming the spectrum to be independent of the tilt angles except as they affect the local incidence angle. Letting \( \alpha \) be the tilt angle in the plane of incidence and \( \beta \) be the tilt angle in the orthogonal direction, he obtained the backscattering coefficient as

\[
\sigma_{pp}(\theta) = 8k^4 \sigma^2 \int \int |G_{pp}(\theta, z_x, z_y)|^2 W(ksin\theta') P(z_x, z_y) dz_x dz_y \tag{3-2}
\]

where \( G_{vv} = \alpha_{vv}(\theta') \)

\[
g_{hh}' = \alpha_{hh}(\theta') + \tan \frac{2 \pi s^2}{2} \tan \frac{\alpha}{\sin \theta'}
\]

\[
P(z_x, z_y) = (2\pi s^2)^{-1} \exp \left( -\frac{z_x^2 + z_y^2}{2s^2} \right)
\]

\[
\alpha^2 \sigma(2ksin\theta') = 0.585 \times 10^{-12} (2ksin\theta')^{-4}
\]

and \( U \) is the windspeed in m/sec measured 12.5 m above sea level. Note that higher order correction terms due to tilting are considered negligible for vertical polarization so that \( G_{vv} = \alpha_{vv}(\theta') \) while for horizontal polarization a correction term is added to \( \alpha_{hh}(\theta') \) to form \( G_{hh}' \). The slope distribution, \( P(z_x, z_y) \), is a simplified form reported by Cox and Munk (1954). From the definition of the sea spectrum it is clear that it is independent of wind speed. Thus, wind dependence in \( \sigma_{pp}(\theta) \) comes only through the slope distribution, \( P(z_x, z_y) \).

Chan and Fung's Model. The model reported by Chan and Fung (1977) for the backscattering coefficient is as follows:

\[
\sigma_{pp}(\theta) = 8k^4 \sigma^2 \int \int |\alpha_{pp}(\theta', \phi)|^2 W(\theta', \phi) P(\theta', z_y') dz_x dz_y \tag{3-3}
\]

which is essentially the same as (3-2) except for the definitions of \( P(z_x, z_y') \) and \( W(\phi, \phi') \) and the fact that higher order corrections to \( \alpha_{pp} \) are ignored. In Chan and Fung (1977) it was shown that the probability of occurrence of a given slope varies with the direction of observation. For this reason
the probability distribution function $P(Zx', Zy')$ reported by Cox and Munk is projected along the look direction first before it is used in the averaging process, i.e.

$$P_\theta(Zx', Zy') = (1 + Zx \tan \theta)P(Zx', Zy')$$  \hspace{1cm} (3-4)$$

In (3-4), $P(Zx', Zy')$ is the slope distribution of the large scale waves as viewed at an incidence angle $\theta$ and is defined in the prime coordinates (Figure 8) whose $x'$-axis is parallel to the wind direction. It is assumed that the plane of incidence is the $XZ$ plane and that the angle between the $x$-axis and the $x'$-axis is $\phi$ so that an upwind observation occurs when $\phi = 0$. In view of Figure 1, the slopes in the primed and the unprimed coordinates are related as follows:

$$Zx' = Zx \cos \phi + Zy \sin \phi$$

$$Zy' = Zy \cos \phi - Zx \sin \phi$$

The form of the slope distribution of a sea surface, $P(Zx', Zy')$, was reported by Cox and Munk (1954) to be

$$P(Zx', Zy') = \frac{F(Zx', Zy')}}{2\pi \sigma_u \sigma_c} \exp \left[ -\frac{Zx'^2}{2\sigma_u^2} - \frac{Zy'^2}{2\sigma_c^2} \right]$$

where

$$F(Zx', Zy') = 1 - \frac{C_{11}}{2} \left( \frac{Zy'^2}{\sigma_c^2} - 1 \right) \frac{Zx'}{\sigma_u} - \frac{C_{03}}{6} \left( \frac{Zx'^3}{\sigma_u^3} - \frac{3Zx'}{\sigma_u} \right)$$

$$+ \frac{C_{40}}{24} \left( \frac{Zy'^4}{\sigma_c^4} - \frac{6Zy'^2}{\sigma_c^2} + 3 \right) + \frac{C_{22}}{4} \left( \frac{Zy'^2}{\sigma_c^2} - 1 \right) \left( \frac{Zx'^2}{\sigma_u^2} - 1 \right)$$

$$+ \frac{C_{04}}{24} \left( \frac{Zx'^4}{\sigma_u^4} - \frac{6Zx'^2}{\sigma_u^2} + 3 \right)$$
Figure 8: Geometry of the problem.
\[ C_{40} = 0.4 \quad C_{22} = 0.12 \quad C_{04} = 0.23 \]

\[ C_{21} = 0.001 - 0.0086U \]

\[ C_{03} = 0.04 - 0.033U \]

\[ \sigma_{u}^2 = \sigma_{s}^2 / (1 + R_{o}) \]

\[ \sigma_{c}^2 = \frac{R_{o} \sigma_{u}^2}{R_{o}} \]

\[ R_{o} = \frac{(0.003 + 1.92 \times 10^{-3}U)/3.16 \times 10^{-3}U}{0.359} \]

\[ \sigma_{s}^2 = \int_{0}^{K_{2}} K^{2}s(K) dK \]

In the expressions above \( U \) is the wind speed in meters per second at an altitude of 12.5 m above the sea horizon. The definition of \( s(K) \) is given in accordance with Pierson (1975) as

\[ s(K) = s_{i}(K), \quad K_{i-1} < K < K_{i} \]

\[ s_{1}(K) = \frac{a}{K^{3}} \exp \left[ -\frac{0.749 g^{2}}{K^{2}U(U_{*})^{3/4}} \right], \quad 0 < K < K_{1} = \frac{K_{2}U_{*}^{2}}{U_{*}^{2}} \]

\[ s_{2}(K) = aK_{1}^{-1/2}K^{-5/2}, \quad K_{1} < K < K_{2} = 0.359 \]

\[ s_{3}(K) = s_{4}(K_{3}) (K/K_{3})^{q}, \quad K_{2} < K < K_{3} = 0.942 \]

\[ s_{4}(K) = 0.875(2\pi)^{1-1} \frac{g + 3gK^{2}/13.169}{(gK + gK^{3}/13.169)(\rho_{1} + 1)/2} \quad K_{3} < K < K_{4} \]

\[ s_{5}(K) = 1.473 \times 10^{-4}U_{*}^{3}K_{6}^{3}K^{-9} \quad K_{4} < K < \infty \]

\( K_{4} \) can be found numerically by setting \( s_{4}(K_{4}) \) equal to \( s_{5}(K_{4}) \).

\[ U_{*} = \text{friction velocity}, \quad U_{*} > U_{*m} \]

\[ K_{m} = (13.1769)^{1/2} \]

\[ q = \log_{10}[s_{2}(K_{2})/s_{4}(K_{3})]/\log_{10}(K_{2}/K_{3}) \]

\[ \rho_{1} = 5.0 - \log_{10}U_{*} \]

\[ z_{o} = 0.684/U_{*} + 4.28 \times 10^{-5}U_{*}^{2} - 4.43 \times 10^{-2} \]

\[ U(U_{*}) = (U_{*}/0.4) \ln (z/z_{o}) \text{ cm/sec} \]

\[ a = 4.05 \times 10^{-3} \text{ cm/sec}^{2} \]

\[ g = 980 \text{ cm/sec}^{2} \]

\[ U_{*m} = 12 \text{ cm/sec} \]
The important characteristics to be noted in this spectral model are:
(i) the spectrum grows with the wind; (ii) in the capillary region defined approximately by \( S_4(K) \) the larger the \( K \) number the faster is the growth (i.e. faster growth of the sea spectrum occurs at larger incident angles and higher frequencies); and (iii) this model is valid to about 38 knots (Pierson and Stacy, 1973). In accordance with Mitsuyasu and Honda, their model can be valid to velocity as high as 33m/sec at 10 meters above the sea horizon. Thus, the theory may be valid to higher wind speed than the 38 knots when operating frequency is such that only their portion of the sea spectrum is the significant contributor.

The relationship between \( S(K) \) and \( W(\theta', \phi) \) can be shown to be (Chan and Fung, 1977)

\[
\sigma^2 W(K, \phi) = \frac{S(K)}{2\pi K} \left[ 1 + 2 \frac{1-R}{1+R} \cos 2\phi \right]
\]

where \( K = 2k \sin \theta' \) and \( R \) is the ratio of the crosswind slope variance to the upwind slope variance. Note that \( R_0 \) is the same as \( R \) except that it is for the large scale waves only. It is believed that \( R \) should be somewhat less than \( R_0 \). However, since the exact expression is not known, the theory is illustrated using Cox and Munk's clean sea model for \( R \). Upon substituting (3-4), (3-5) into (3-3) we obtain

\[
\sigma^2 W(\theta, \phi) = \int \int \int \frac{2}{\pi} k^3 \left| \alpha_{pp} \right|^2 \left[ 1 + \frac{2(1-R)}{1+R} \cos 2\theta' \right] \frac{S(2k \sin \theta')}{\sin \theta'} (1 + Z_x \tan \theta) P(Z_x', Z_y') dZ_x dZ_y
\]

(3-6)
Equation (3-2) and (3-6) represent the two different types of sea scatter theory considered in this paper. Note that the lower limit for Zx in (3-6) is $-\cot \theta$ instead of minus infinity. This is necessary in order to avoid looking at the back side of a facet. As a result, the probability density function should be renormalized with respect to this range of limit which varies with the incident angle.

C. Comparison with Sea Scatter Measurements

1. Comparison of $\sigma^0(\theta, \phi)$ versus Azimuth

The $\sigma^0(\theta, \phi)$ versus $\phi$ data reported by Jones and Schroeder (1977) are all at $30^\circ$ incidence angle. Comparisons between Chan and Fung's theory and these data are shown in Figure 9a and 9b for the vertically and horizontally polarized cases respectively. Wright's theory is not shown since it does not include azimuth dependence. In making these comparisons, the absolute levels of $\sigma^0_{vv}$ and $\sigma^0_{hh}$ at different wind speeds are disregarded. It is seen that satisfactory agreement is obtained for the variations of $\sigma^0$ versus $\phi$ for wind speeds at 6.5 m/sec and 15 m/sec and for both polarizations. As will be shown in $\sigma^0(\theta, \phi)$ versus wind speed comparisons in Figure 10, it is rather meaningless in most cases to compare the absolute levels of $\sigma^0(\theta, \phi)$ at a single incident angle, polarization, and wind speed. This comes about because of the unavoidable scatter which is always associated with limited amount of data.

2. Comparison of $\sigma^0(\theta, \phi)$ Versus Wind Speed

Figure 10a, b, and c, show the comparisons between $\sigma^0$ data reported by Jones and Schroeder (1977) and $\sigma^0_{hh, vv}(\theta, \phi)$ computed using (3-2) and (3-6) versus wind speed at 19.5 m above the sea horizon for downwind and crosswind cases respectively at incidence angles $30^\circ$, $40^\circ$, and $50^\circ$. In these comparisons the computed absolute levels

VV Theory
Data

HH Theory
Data
of $\sigma_{hh,vv}^{0}(\theta,\phi)$ are retained. The range of wind speeds considered is approximately between 6.2 m/sec and 15 m/sec. It is noted that the reason why $\sigma_{vv}^{0}(\theta,\phi)$ is much higher in level than $\sigma_{hh}^{0}(\theta,\phi)$ is the inherent characteristics of the first order perturbation theory. While the AAFE data are limited, they seem to agree with the predicted theoretical level separation. Also, uncorrected data, Figures 11a and b, taken from Skylab SL-2 and SL-3 at 43° and 50° do show a clear level separation of the predicted order of magnitude. Note that data selected from Skylab are those taken during Hurricane Ava and Tropical Storm Christine, where a continuous measurement of $\sigma^{0}$ versus wind speed, was available. Despite clear differences at particular incident angles and wind speeds, a general agreement in absolute levels in wind speed trends and in incident angle variations is observed.

Also included in Figures 10a and 10b are the theoretical predictions from Wright's theory. It is seen that $\sigma^{0}$ exhibits much less dependence on wind speed. This appears to be due primarily to the use of Phillips' sea spectrum model which is independent of the wind speed. Recent studies on the hydrodynamic effects of the long and the short wave interactions may serve as another explanation for the observed increase in $\sigma^{0}$. However, since non-linear interaction is of higher order, it does not seem likely that a full explanation can be made in terms of this effect alone. In view of the fact that the measured $\sigma^{0}$ values do increase significantly with the wind, it appears that the two-scale scatter theory cannot provide correct predictions unless the sea spectrum is allowed to increase with the wind speed.

D. Conclusions

When an appropriate sea spectrum and sea-surface slope distribution for the large scale waves are incorporated, the two-scale scatter model appears to provide satisfactory explanations of the variation of the scattering coefficients versus polarization, azimuth, and wind speed.

**Downwind**

$f = 13.9$ GHz

$\theta = 50^\circ$
4.0 CONCLUSIONS AND RECOMMENDATIONS

The 1975 JONSWAP circle flight data appears to be adequately modelled by

\[ \sigma^o(U,\theta,\phi_w) = A_0(U,\theta) + A_1(U,\theta)\cos(\phi_w) + A_2(U,\theta)\cos(2\phi_w) \]  (2-3a)

The coefficients of this model, determined through regression analysis were shown to be related to wind speed by

\[ A_n(U,\theta) = \rho_n(\theta) U^n \]  (2-4)

However, previous circle flight data sets exhibit an asymmetry not accommodated by this model, Afarani (1975). Explanations for these observations include both experimental problems and the possibility that they are caused by the effect of underlying wave or swell trains traveling in a direction different from the wind direction. The difficulty of making such measurements from an aircraft cannot be overestimated. Not only must the aircraft maintain a constant altitude during the circle, but either the wind conditions must be the same at all points in the five-mile diameter circle or some kind of correction must be made for differences that can only be inferred because wind measurements are made at a point near but not in the circle. Consequently, measurements from a tower seem in order since the wind can be measured on the tower and no observation point is far enough away to be in a different wind field.

The feasibility of the WINDVEC inversion algorithm to determine the wind speed and direction from the orthogonal scattering measurements was demonstrated. In this algorithm, an estimate of the wind speed is obtained from the average of the radar cross section by the power-law relationship.

\[ \hat{U} = a(\theta) \sigma^o_{AV} \gamma(\theta) \]  (2-7)
Using this estimated wind speed values for the $A_n$ coefficients in (2-3a) can be obtained. Clearly, the only remaining unknown in this expression is the wind direction, which can be solved for by

$$
\phi_w = \cos^{-1} \left\{ \frac{-A_1 \pm \sqrt{A_1^2 - 8A_2(\hat{A}_0 - \hat{A}_2 - \alpha^o)}}{4A_2} \right\}
$$

This yields two estimates for the wind direction, one in the first quadrant and the other in the second. These values are mirrored to obtain values in the third and fourth quadrant, respectively. The estimates of wind direction from the fore and aft beam are corrected to North and then averaged to improve the wind direction estimate. Vertical polarization estimates of both wind speed and direction are considerably better than those for horizontal polarization.

Satisfactory application of this inversion to SASS (SeaSat Active Scatterometer System) will require a larger data bank with a wider range of incidence angles. At present sufficient good data exists only for $\theta = 40^o$. Consequently, before SeaSat launch there is a need for more experimentation, either tower or aircraft, so that optimum advantage can be obtained from its data.

Also, comparison between different scattering theories and scatterometer measurements have shown different results. First, better agreement is obtained when the slope distribution reported by Cox and Munk is projected along the look direction before it is used in the averaging process. Second, use of a sea spectrum which grows with wind speed also yields more satisfactory results.

APPENDIX D

Wind Direction Errors Obtained Using WINDEX

Wind Direction Error:

(PHIERR) vs $\phi$

A. Direction errors using antenna 1.
B. Direction error using antenna 2.

Wind Direction Error:

(ERRAUG) vs $\phi$

A. Direction errors using averaged estimates.
Flight 13
Incidence Angle: 40°
Polarization: HH

Correlation: -0.193
