ABSTRACT

Processes which lead to the production of γ rays with energy greater than 8 MeV in solar flares are reviewed and evaluated. Excited states which can be produced by inelastic scattering, charge exchange, and spallation reactions in the abundant nuclear species are considered in order to identify nuclear lines which may contribute to the γ-ray spectrum of solar flares. The flux of 15.11-MeV γ rays relative to the flux of 4.44-MeV γ rays from the de-excitation of the corresponding states in $^{12}\text{C}$ is calculated for a number of assumed distributions of exciting particles. This flux ratio is shown to be a sensitive diagnostic of accelerated particle spectra. Other high-energy nuclear levels are not so isolated as the 15.11-MeV state and are not expected to be so strong. The spectrum of γ rays from the decay of $\pi^0$ is shown to be sensitive to the energy distribution of particles accelerated to energies greater than 100 MeV.
I. INTRODUCTION

In astronomical observations, as well as in laboratory measurements, γ-ray lines serve as probes of energetic particle interactions. Solar γ-ray lines were first detected from the Importance 3B solar flares of 1972 August 4 and 7 by Chupp et al. (1973) with the γ-ray spectrometer aboard the OSO-7 satellite. Theoretical treatments of γ-ray production made prior to 1972 have been reviewed by Ramaty, Kozlovsky and Lingenfelter (1975). They present, in addition, updated interpretations of γ-ray observations, relating them to the spectrum, number, and energy content of accelerated particles.

The solar γ-ray spectrum in the energy range 4 to 8 MeV has been studied further by Ramaty, Kozlovsky and Suri (1977) with the conclusion that the emission in that energy range is due almost entirely to nuclear processes, and that the ratio of electrons to protons does not exceed 5%. They suggest that the observations are best fit by a relatively flat spectrum of particles whose velocity vectors do not point predominantly towards the photosphere.

Because most of the higher energy states are particle unstable and lead to little or no γ-ray emission, the significance of γ-ray lines more energetic than the 7.12-MeV line of $^{16}\text{O}$ has only recently been considered (Crannell and Crannell 1976, 1978; Crannell, Ramaty and Crannell 1977). The information to be gained from observations of a high-energy γ-ray line should not, however, be overlooked. Pairs of γ-ray lines,
from the same nuclear species but resulting from the de-excitation of nuclear levels with widely separated thresholds, provide a unique measure of the spectra of high-energy particle within their source.

In the present work, the γ-ray line emission and continuum radiation above 8 MeV are investigated. A number of nuclear states are identified as possible candidates for producing high-energy γ-ray line emission. For one high-energy line, resulting from the decay of $^{12}_C^*(15.11 \text{ MeV})$, the excitation cross sections and branching ratios have been studied extensively. These measured cross sections and branching ratios are used to calculate the expected intensity of the 15.11-MeV line emission relative to that of the 4.44-MeV line from a lower-lying state in $^{12}_C$.

If the spectrum of energetic charged particles extends with sufficient intensity to hundreds of MeV/nucleon in solar flares, high-energy gamma radiation will result from the production and decay of $\pi^0$ mesons. The spectra of $\pi^0$-decay γ rays have been calculated by Lingenfelter and Bamby (1967) and by Chung (1972) with the approximation that all $\pi^0$ mesons are produced at the mean $\pi^0$ energy for the given incident proton energy. In the present work, the total flux of $\pi^0$ mesons is re-evaluated and the resultant γ-ray spectra are calculated from measured differential cross sections for $\pi^0$ production.

In the next section, the nuclear processes which contribute to line emission and continuum radiation above 8 MeV are described in detail and the relative flux densities are determined.
The resultant γ-ray spectrum, with an estimated upper limit for the bremsstrahlung contribution, is presented in Section III. In the final section, the significance and observability of the predicted spectrum are summarized.
II. NUCLEAR PROCESSES

The strength of γ-ray line emission is proportional to the product of three factors: cross section, branching ratio, and nuclear abundances. Abundances are relatively well known and branching ratios for electromagnetic decay have been determined adequately for most of the states of interest. The cross sections for production of most high-energy states are, however, sparsely measured. One of the well-studied γ-ray transitions, which is also one of the strongest, is produced by decay of the 15.11-MeV state in $^{12}$C. In the subsection that follows, the technique for predicting the strength of the 15.11-MeV line relative to that of the 4.44-MeV line is developed, and predictions based on measured cross sections and branching ratios are presented. In Subsection b, the strengths of other γ-ray lines with energies above 8 MeV are compared to the strength of the 15.11-MeV line. The processes which can be expected to make significant contributions to the γ-ray continuum above 8 MeV are bremsstrahlung and π⁰ decay. In Subsection c, the relevant cross sections for production of neutral pions are presented, and the spectral distribution of the subsequent γ-ray continuum is evaluated.

a) Gamma Rays from the 15.11-MeV State in $^{12}$C

With one exception, all excited states in the nucleus $^{12}$C with energies above the threshold for alpha emission at 7.367 MeV decay predominantly by direct particle emission and thus produce few nuclear γ rays. The one exception is the lowest-
energy isospin $T = 1$ state, the analog to the ground state in $^{12}$B and $^{12}$N, at 15.11 MeV. This state lies below the lowest-energy, single-particle emission threshold by 0.85 MeV and is thus stable against neutron or proton emission. If this level were a pure $T = 1$ state, decay by alpha emission would be forbidden by isospin conservation. There is a small admixture of $T = 0$ in this state, but the measured alpha- to gamma-decay branching ratio is only $0.041 \pm 0.009$ (Balamuth, Zurmühl and Tabor 1974). Because electromagnetic transitions can change the nuclear isospin by 1 unit, the state can decay readily by emission of a $\gamma$ ray. In the case of 15.11-MeV excitation, the decay directly to the ground state is dominant. A weighted average of the experimentally measured branching ratios (Ajzenberg-Selove 1976) yields a value of $0.952 \pm 0.009$. Thus de-excitation of the 15.11-MeV state in $^{12}$C proceeds by $\gamma$-ray emission directly to the ground state $91 \pm 2\%$ of the time.

The important cross sections for producing 4.44- and 15.11-MeV $\gamma$ rays are shown in Figure 1 as a function of the kinetic energy of the incident particle. In the present analysis, the cross sections for producing 4.44-MeV $\gamma$ rays by proton interactions are taken from the work of Ramaty, Kozlovsky, and Suri (1977) which includes measurements up to 103 MeV. Their results are represented by the solid curve. At low energies, this curve is a smoothed average of the $^{12}$C(p,p') $^{12}$C*(4.44 MeV) cross section. At higher energies, it includes important contributions due to production of a 4.44-MeV state in $^{11}$B from the reaction $^{12}$C(p, 2p) $^{11}$B*(4.44 MeV). The cross sections for producing
4.44-MeV γ rays by alpha-particle interactions are also taken from the work of Ramaty, Koslovsky, and Suri (1977) represented by the dashed curve. This is an important process in the solar medium because of the magnitude of the cross section and because of the abundance of alpha particles.

The dotted curve showing some of the structure in the cross section for production of 4.44-MeV γ rays by proton interactions with $^{12}$C is obtained from the data of Martin, Schneider and Semper (1953) for $4.4 \leq E_p \leq 6.5$ MeV; Reich, Phillips and Russell (1956) for $4.4 \leq E_p \leq 5.5$ MeV; Barnard, Swint and Clegg (1966) for $6.6 \leq E_p \leq 11.6$ MeV; and Nagahara (1961) for $9.5 \leq E_p \leq 16$ MeV, where $E_p$ is the kinetic energy of the incident proton. Up to an energy of 19 MeV, the cross section for excitation of the 4.44-MeV state in $^{12}$C shows considerable structure. In the works of Martin, Schneider and Semper and of Reich, Phillips and Russell, the excitation cross section was measured by detecting the 4.44-MeV de-excitation γ ray at 90°. The total cross section represented by the dotted curve was obtained by assuming that the cross section for photon emission is isotropic. Differential cross sections measured at additional angles by Reich, Phillips and Russell at three energies near the first resonance, 5.188, 5.297, and 5.425 MeV, show that this assumption of isotropy leads to discrepancies as large as 60% in the first two resonances. In the experiments of Barnard, Swint, and Clegg and of Nagahara, differential cross sections were measured for a wide range of angles of the recoil proton at each incident proton energy. The
cross sections shown here as the dotted curve include the total cross sections given by those authors.

The cross sections obtained with alternate methods, by detecting the scattered proton and by detecting the de-excitation γ ray, give satisfactory agreement within the limitations of the experimental measurements. The resonance structure, which would be important for narrow distributions of proton energies, is effectively smoothed when folded with the proton spectra assumed for purposes of the present work.

The total cross sections for production of the 15.11-MeV state in 12C by protons has been measured by a number of workers. The dotted line shown in Figure 1 indicating the 15.11-MeV excitation in 12C is taken from the 12C(p, p'γ) 12C*(15.11 MeV) measurements of Warburton and Funsten (1962) for 14 ≤ E_p ≤ 20 MeV, and from Neasday et al. (1963) for 14 ≤ E_p ≤ 48 MeV. In both of these experiments the 15.11-MeV γ ray was detected only at 90° in the laboratory. The total proton excitation cross sections plotted in Figure 1 were obtained by assuming that the γ-ray emission is isotropic in the laboratory and by reducing by 0.8 and 0.9 the results of Warburton and Funsten and of Neasday et al., respectively, to obtain agreement with the measurement of Scott, Fisher and Chant (1967) for an incident proton energy of 21 MeV.

Above a proton energy of 20 MeV, 12C(p, p'γ) 12C*(15.11 MeV) differential cross sections have been measured by Scott, Fisher and Chant (1967) for proton energies between 20.5 and 30.3 MeV, Geramb et al. (1975) for 22.5 ≤ E_p ≤ 45 MeV, Dickens, Haner and
Waddel (1963) at 31 MeV, Petersen et al. (1967) at 46 MeV, Amos et al. (1974) at 61 MeV, and Hasselgren et al. (1965) at 185 MeV. The differential cross sections reported by these authors have been integrated to obtain the total cross section shown in Figure 1. The total cross section obtained from the work of Hasselgren et al. of 0.5 mb is not shown in Figure 1, but was used in the analysis. For proton energies above 24 MeV these cross sections fall above those given by the dashed curve representing the measurements of Warburton and Funsten. This is almost certainly due to the nonisotropic nature of the 15.11-MeV γ-ray emission.

Other nuclear reactions which produce the 15.11-MeV state are significantly reduced when compared to inelastic proton scattering. The excitation of the 15.11-MeV state by alpha particles has been observed (Spuller et al. 1975) but is suppressed by more than an order of magnitude due to the parity and isospin of the state, and is thus not important in stellar processes. The cross sections for $^{16}O(p,p'\alpha)\; ^{12}C*(15.11 \text{ MeV})$ have not been reported in the literature. Preliminary measurements of the ratio of this cross section to the cross section for the direct process $^{12}C(p,p')\; ^{12}C*(15.11 \text{ MeV})$ (Lapides et al. 1978) have shown that it is approximately the same as the equivalent ratio for producing the 4.44-MeV state in $^{12}C$. Thus these secondary reactions on $^{16}O$ are expected to enhance the intensities of both lines without significantly altering the ratio of line intensities. For consistency, all $(p,p'\alpha)$ interactions are omitted in the following considerations.
The solid curves shown in Figure 1 are visual fits to the excitation cross section data. Above a proton kinetic energy, $E_p$, of 30 MeV, the cross sections for excitation of both the 4.44- and 15.11-MeV states decrease approximately as $1/E_p$.

The cross sections represented by the solid lines, along with interpolations between the higher-energy measurements, were employed in arriving at the flux estimates presented in this paper.

As is made clear in Figure 1, the cross sections for production of the two nuclear states have different energy dependencies, and thus the relative intensities of the 15.11-MeV and 4.44-MeV lines depend on the functional form of the energy spectra of incident protons and alpha particles. In this work the energy spectrum is parameterized by two variables as in the solar $\gamma$-ray review of Ramaty, Kozlovsky, and Linkenfelter (1975). The energy in the particle spectrum is assumed to be constant from 0 to some cutoff energy $E_c$, and then to decrease with a power law with exponent $s$, or

$$
\frac{dN_p}{dE_p} = \begin{cases} 
C, & R \leq E_c \\
C \left( \frac{E_c}{E_p} \right)^s, & R > E_c
\end{cases}
$$

The ratio of alpha particle to proton flux is assumed to be 0.07, in accord with abundances given by Trimble (1975). The ratios of the fluxes of the two lines, $\xi(15.11)/\xi(4.44)$ is thus
given by the expression
\[
\frac{\phi(15.11)}{\phi(4.44)} = 0.91 \int_0^{E_c} \sigma_{15.11}(p,p') \nu \left( \frac{dN}{dE_p} \right) dE_p + 0.07 \int_0^{E_c} \sigma_{4.44}(\alpha,\alpha') \nu \left( \frac{dN}{dE_p} \right) dE_p,
\]
where \(\sigma_{15.11}(p,p')\) and \(\sigma_{4.44}(p,p')\) are the cross sections for producing the 15.11- and 4.44-MeV states in \(^{12}\text{C}\) by proton collisions, \(\sigma_{4.44}(\alpha,\alpha')\) is the cross section for producing the 4.44-MeV state by alpha collisions, and \(\nu\) is the velocity of the incident particle. In Figure 2 the ratio predicted by Equation (2) is plotted as a function of \(s\) for four different values of \(E_c\) ranging from 0 to 30 MeV. For the more probable cases with \(E_c \geq 20\) MeV (Ramaty, Kozlovsky, and Suri 1977) the intensity of the 15.11-MeV line is greater than 1% of the 4.44-MeV line for all values of \(s\).

b) Gamma Rays from Other Nuclear States above 8 MeV

Production of \(\gamma\)-ray lines above an energy of 8 MeV in the solar atmosphere is restricted by the scarcity of high-energy \(\gamma\)-ray transitions associated with the small number of relatively abundant isotopes. In the present work, excited states which can be produced by inelastic scattering, charge exchange, and spallation reactions in the abundant nuclear species have been considered. Since even the 15.11-MeV line will be difficult to detect with present instrumentation, only those lines which have a relative intensity of at least 5% of the 15.11-MeV line are tabulated here.
Three factors other than the spectrum of incident particles are important in determining the relative strengths of nuclear lines: first, the relative abundance of the target nuclei; second, the cross section for producing the excited state; and third, the branching ratio for electromagnetic decay of the excited state to a suitable level. For most nuclei, cross sections for production of any of the high-energy states are known only at a few selected energies, if at all. Those inelastic scattering cross sections which have been determined are within a factor of three of the cross section for producing the 15.11-MeV state in $^{12}$C. Spallation and charge exchange cross sections ($p,n$) are generally smaller. For purposes of this investigation, therefore, it is assumed that none of the unknown cross sections is significantly greater than that for the 15.11-MeV state in $^{12}$C, and hence only those nuclei with moderate abundances relative to $^{12}$C have been considered. The nuclear species with abundances greater than 1% that of $^{12}$C and their relative abundances in the solar photosphere (Trimble 1975) are presented in Table 1.

In order for an excited state to exhibit a significant $\gamma$-ray branching ratio, it must be particle stable. Thus all states above the single-nucleon threshold have been ignored. States above the alpha-particle threshold also were ignored unless alpha decay is forbidden by isospin considerations. The list of excited states is further restricted to those which can be excited by relatively simple reactions with the abundant nuclei listed in Table 1. These reactions are $(p,p')$, $(p,2p)$,
(p,d), (p,p',α), (p,n), (α,α'), and (α,γ). Hydrogen has no excited nuclear states below the delta resonance at 294 MeV. This resonance does decay by γ-ray emission 0.6% of the time but does not produce line emission because of its intrinsic width of 115 MeV. The excited states in helium are all above the particle disintegration threshold. Furthermore, γ-ray transitions from the first three excited states, which lie in the energy range 19 to 23 MeV, are either forbidden or inhibited by the spin and the parity of the nuclear states. In oxygen and iron there are no particle-stable nuclear levels above 8 MeV.

In Table 2 a list of the energies of strong γ-ray transitions together with the excited nuclei and the γ-ray branching ratios (Ajzenberg-Selove 1972, 1975, 1976, 1977; Ajzenberg-Selove and Lauritsen, 1974; Auble, 1977; Endt and Van der Leun 1973; Fiarman and Hanna 1975; Fiarman and Meyerhof, 1973) are presented. For the most part, the γ rays are the result of transitions from an excited nuclear state to the ground state. In a few cases, those marked with an asterisk, the dominant transition is to the first excited state of the nucleus. The last column labeled "strength factor" gives the product of the γ-ray branching ratio times the relative abundance of the target nucleus, normalized to a value of 100 for the 15.11-MeV transition in 12C. If the total (p, p') cross sections were the same for each of these states, the relative intensities of the γ-ray emissions would be directly proportional to the strength factors listed. The cross sections for the spallation reactions, on the other hand, are generally more than an order of magnitude
lower than the inelastic scattering cross sections. Strength factors for these transitions would, therefore, be misleading in relationship to the γ-ray flux. For this reason, strength factors for those transitions produced by spallation reactions are not listed in Table 2. It is not expected that the γ-ray flux from any of the transitions listed in Table 2 will exceed 30% of that of the 15.11-MeV line.

Two additional lines, with branching ratios less than 40%, are included in Table 2 because both are produced by transitions in $^{12}$C and because their intensities relative to the 15.11-MeV line are well known. The 15.11-MeV state decays to the 4.44-MeV state, producing a line at 10.67 MeV with a flux 3% that of the 15.11-MeV line. The state at 12.61 MeV, ($1^+$, T = 0) is known to decay electromagnetically to the ground state 2% of the time (Ajzenberg-Selove 1976). The cross sections for production of this state are not as well measured as those for the 15.11-MeV state, but values for the cross section have been reported by Measday et al. (1963) for 14.9 < E_p < 19 MeV, and Geramb et al. (1975) for 24 < E_p < 45 MeV. Under the assumption that the proton spectrum is constant up to an energy $E_c$ = 30 MeV, the integral production rate of the 12.71 MeV state, based on these cross sections, is found to be a factor of 3 greater than that for the 15.11-MeV state. The 12.71-MeV level in $^{12}$C would therefore produce a line with approximately 6% the strength of the 15.11-MeV line.

A summary, indicating the number of γ-ray transitions by energy and by excited nuclear species, is presented in Table 3.
It is readily seen that the total number of lines is a decreasing function of energy, with most of the transitions having energies less than 10 MeV. The only known γ-ray line above 13 MeV is the well resolved and isolated transition due to the 15.11-MeV state in $^{12}$C. Other possible sources of γ-ray line emission at energies characterizing the nuclear binding energy, approximately 8 MeV, are reactions involving thermal neutron capture. These (n,γ) reactions have not been considered in this work, but are known to be powerful diagnostics in remote sensing, as discussed by Trombka et al. (1978).

c) Production of $\pi^0$ Mesons

Stocker (1970, 1973) has compiled the $\pi^0$ production cross sections times multiplicities for the reactions

$$p + p \rightarrow n\pi^0 + \text{anything},$$

and

$$p + \alpha \rightarrow n\pi^0 + \text{anything},$$

where $n$ is the $\pi^0$ multiplicity. The paramaterized fit (Stocker 1973) for $\pi^0$ production by proton-proton interactions covers a range of energies from a few hundred up to greater than $10^6$ MeV, applicable to the cosmic ray particle spectrum. The spectrum of particles accelerated in solar flares is not expected to extend significantly above an energy of $10^3$ MeV, so that the range of energies from production threshold to cutoff is relatively narrow. As can be seen in Figure 3, the cross section for the reaction $p + p \rightarrow p + p + \pi^0$ rises rapidly in this range, then flattens abruptly, remaining constant up to an energy above the
two-pion production threshold. It is precisely in this range that the parameterized fit based on a much wider energy range is poorest, differing from the measured values by as much as a factor of two. The experimental points of Baldoni et al. (1962) and of Bugg et al. (1964) have been included in Figure 3 along with those referenced by Stecker (1973). For purposes of the present work, the π⁰ production rates have been evaluated from a numerical integration of the smooth curve drawn through the measured points shown as the solid line in Figure 3. As no additional measurements are available for π⁰ production from proton-alpha interactions, the values reported by Stecker (1970) have been employed in the present work.

The proton-alpha particle interactions have a lower threshold for π⁰ production than the proton-proton interactions. The importance of proton-alpha particle interactions is further enhanced by energetic alpha particles which interact with ambient solar protons. In the present analysis, the differential alpha-particle flux is assumed to scale as the relative abundance times the differential proton flux as a function of kinetic energy per nucleon. The total contribution of proton-alpha plus alpha-proton is then twice the π⁰ yield due to proton-alpha particle interactions. The abundances given in Table 1 have been assumed for the relative number of alpha particles per proton. In Table 4, the fractional contributions due to proton-proton and to proton-alpha plus alpha-proton interactions are shown for three values of the energetic particle spectral index. The increasing importance of the lower-energy particles
and consequently the lower-threshold proton-alpha and alpha-proton reactions, action of increasing spectral index, can be seen from a comparison of the relative contributions to the energy ranges above and below 700 MeV/nucleon.

The spectra of π⁰ γ rays shown in Figure 4 have been calculated from detailed differential cross sections for π⁰ production available for proton kinetic energies of 560 MeV (Baldoni et al. 1962) and 970 MeV (Bugg et al. 1964). The expected solar γ-ray spectra can be represented well by mixtures of the spectra for these two proton energies, weighted in proportion to the fractional contributions due to incident energetic particles in the two ranges of kinetic energy: ≤ 700 and > 700 MeV/nucleon.
III. CONTINUUM AND LINE EMISSION ABOVE 8 MeV

The predicted spectrum of solar-flare γ-ray emission is summarized in Figure 5. The observed nuclear-line emission and continuum radiation in the 1972 August 4 solar flare have been employed for normalization (Chupp, Forrest, and Suri 1975; Suri et al. 1975). The expected line emission at 15.11 MeV and the continuum radiation due to π⁰ decay are based on calculated cross sections and multiplicities presented in the previous section.

The 4.44-MeV line emission observed in the 1972 August 4 flare is shown in Figure 5, normalized to that differential flux expected for an idealized line width of 90 keV, FWHM. This is the expected width of the line due to Doppler broadening alone, calculated by Ramaty, Kozlovsky, and Suri (1977) under the simplifying assumption that there is no correlation between the direction of the incident proton and the emitted γ ray.

The corresponding 15.11-MeV line emission is shown for a Doppler width of 300 keV and an instantaneous proton spectrum which is constant up to an energy of 30 MeV and which decreases with a spectral index of 2 above that energy. Both the 4.44- and the 15.11-MeV line emission are insensitive to steepening of the proton spectrum above 100 MeV. In addition to line emission at 15.11 MeV, continuum radiation with the same total flux is expected from the interactions of energetic carbon nuclei with the ambient solar medium.

The continuum radiation reported by Suri et al. (1975) in the energy interval 1 to 7 MeV for the 1972 August 4 flare are shown as data points with associated statistical uncertainties.
in Figure 5. The total flux observed in the interval 4 to 8 MeV, including both line emission and continuum radiation, is 0.2 photons cm$^{-2}$ s$^{-1}$, one third of which is reportedly observed in the 4.4-MeV and 6.1-MeV lines (Chupp et al. 1975). Calculations by Rumaty, Kozlovsky, and Suri (1977) suggest that all of the observed emission above 4 MeV is of nuclear origin, with the continuum radiation resulting from Doppler-broadened γ-ray lines. Such extreme Doppler broadening is thought to be due to the de-excitation of energetic heavy nuclei which have been accelerated in solar flares. These nuclei are excited by interactions with the ambient solar medium and decay before slowing down.

The possible contribution of electron bremsstrahlung to the γ-ray continuum above 8 MeV has been estimated under the assumption that the contribution for energies between 4 and 8 MeV is at most half of the total observed flux. Because best estimates indicate that electron bremsstrahlung above 4 MeV is entirely negligible, half the observed flux may be considered a very generous upper limit. The high-energy bremsstrahlung spectrum is normalized in the interval 4 to 8 MeV and extrapolated with a spectral index of 3, as shown in Figure 5. For the energy range under consideration, an index of 3 for the photon spectrum corresponds to an instantaneous electron spectrum with a power-law index slightly less than 3, a typical value for the spectra of electrons observed in a large number of solar flares (Datlowe 1971).

The yield of π$^\circ$ γ-rays per flare proton has been calculated for proton-proton interactions using the π$^\circ$ production cross
sections times multiplicities presented in Figure 3. For proton-alpha particle interactions, the yield of \( \pi^0 \) \( \gamma \) rays has been calculated from the \( \pi^0 \) production cross sections times multiplicities given for this process in Figure 5 of Stocker (1970). The \( \pi^0 \) \( \gamma \)-ray yield has been normalized to the number of protons required to produce the 4.44-MeV \( \gamma \)-ray flux observed in the 1972 August 4 flare.

The \( \gamma \)-ray continuum due to \( \pi^0 \) decay has been calculated for three cases. In each, the instantaneous proton spectrum is assumed to be constant up to an energy of 30 MeV and to follow a power law in energy with a spectral index of 2 for energies between 30 and 100 MeV. In the first case, the proton spectrum is assumed to continue with a spectral index, \( s \), of 2 up to an energy of \( 10^3 \) MeV, at which the spectrum is terminated and the proton flux is set equal to zero. In the other two cases, the spectrum is assumed to break at \( 100 \) MeV and to drop with a spectral index of 3 or 4 up to an energy of \( 10^3 \) MeV, at which it is again terminated. The resultant spectra of \( \gamma \) rays due to \( \pi^0 \) decay are shown in Figure 5.
IV. SUMMARY

The γ-ray spectrum above 8 MeV is a rich and relatively unexplored region which is populated by emission from the highest-energy interactions in solar flares. The large number of γ-ray emitting levels in the energy interval between 8 and 10 MeV will make a significant contribution to the continuum emission. Line emission with relatively narrow Doppler widths may be expected to be accompanied by greatly broadened line emission due to excitation of accelerated heavy ions which interact with the ambient solar atmosphere. The density of possible γ-ray lines between 8 and 10 MeV, all with similar strength factors, will increase the difficulty of resolving and identifying the individual lines. Accurate predictions of the relative strengths of these lines will require a much better knowledge of the important cross sections. Because of their sensitivity to the spectrum of energetic flare particles, identification of any of these high-energy γ-ray lines would provide significant, new constraints on the energetics of solar flares.

Line emission from the 15.11-MeV excited state of $^{12}\text{C}$ is shown to be a sensitive measure of the energy spectrum of the protons accelerated in solar flares. The results presented in Figure 2 demonstrate that the flux of 15.11-MeV γ rays relative to the flux of 4.44-MeV γ rays is a strong function of the characteristics of the proton spectrum in the energy range 10 to 100 MeV. Uncertainties in the expected spectral dependence of the flux ratio are due primarily to lack of measured cross sections for the process $^{16}\text{O}(p,p'\alpha)\ 12\text{C}^{*}(15.11\text{MeV})$. A knowledge of these cross sections is required for accurate
quantitative interpretations of solar flare observations.

Observability of the 15.11-MeV line depends on the intensity of the line emission, the intensity of other emission within the band pass defined by the width of the line, and the instrumental resolution and sensitivity with which it is observed. The continuum radiation in an energy interval around 15.11 MeV is expected to be low and not to limit the observability of the line. The detection probability of 15.11-MeV γ rays is enhanced by the high interaction cross section, which rises in this energy range due to the pair-production process. The energy resolution characteristic of NaI scintillation spectrometers for γ rays in this energy range is less than the expected Doppler width of the line, so that no severe constraints on the instrumental resolution are required. For flare intensities comparable to the 1972 August 4 solar flare, detectors with 10 times the sensitive area of the OSO-7 instrument, or approximately 500 cm², and 100% duty factor, continuous solar viewing, would enable positive detection of the 15.11-MeV line or definitive restrictions on the spectrum of flare protons.

Observations of γ rays resulting from the production and decay of π⁰ would provide clear evidence that nuclei are accelerated to kinetic energies of many hundreds of MeV/nucleon in solar flares. Even with spectra cut off at 10⁷ MeV, more than 40% of the π⁰-decay γ rays are due to interactions with particles of kinetic energy greater than 700 MeV/nucleon. Interactions involving alpha particles contribute nearly 50% of the π⁰ γ rays, independent of the spectral index. Measurements of π⁰-production
cross sections for proton-alpha particle interactions are required for experimental confirmation of the calculations on which the present work is based.

Observability of π° γ rays depends on flare intensity and detector sensitivity. The energy resolution available with both NaI and CsI scintillation spectrometers is more than adequate to resolve the general features of the expected spectrum. No other continuum radiations are expected to confuse the observations. The detection probability for these γ rays is high due to the pair production cross section. The actual detector areas required depend on details of instrumental shielding and background. Areas of approximately 500 cm², however, should enable positive observations for a proton spectral index of 3 or less, and definitive upper limits if the spectrum falls off more steeply.
V. ACKNOWLEDGEMENTS

The authors thank Mr. Roger Bussard for assistance in the compilation of the $\pi^-$ cross sections, and Dr. Evans Hayward for fruitful discussions at the beginning of this work. Extensive use has been made of the Compilation of NN and ND Interactions, prepared by the UCRL Particle Data Group.

FIGURE CAPTIONS

Figure 1. Cross sections for $^{12}\text{C}(p,p')$ and $^{12}\text{C}(p,p')$ as a function of the kinetic energy of the exciting proton.

Figure 2. Ratio of the flux of 15.11-MeV to the flux of 4.44-MeV $\gamma$ rays as a function of the spectral index of the exciting proton.

Figure 3. Cross sections times multiplicity for the production of $\pi^0$ as a function of the kinetic energy of the exciting proton. References are given by first author only.

Figure 4. Spectra of $\gamma$ rays resulting from the decay of $\pi^0$ produced by proton beams of kinetic energies 560 and 970 MeV.

Figure 5. Gamma-ray line emission and continuum radiation for a differential proton spectrum of the form $dN_p/dE_p \propto E_p^{-s}$ with $s = 0$ for $E_p < 30$ MeV and $s = 2$ for $30 < E_p < 100$ MeV. The calculated fluxes are normalized to the line emission and continuum radiation observed below 8 MeV in the 1972 August 4 solar flare. Three estimates of the $\gamma$-ray continuum due to $\pi^0$ decay are presented, one with a proton spectrum which continues above 100 MeV with a power-law index of $s = 2$. The others break at 100 MeV, continuing with power-law indices of $s = 3$ or 4. All three are cut off at an energy of 1000 MeV.

\end{figure}
Processes which lead to the production of \( \gamma \) rays with energy greater than 8 MeV in solar flares are reviewed and evaluated. Excited states which can be produced by inelastic scattering, charge exchange, and spallation reactions in the abundant nuclear species are considered in order to identify nuclear lines which may contribute to the \( \gamma \)-ray spectrum of solar flares. The flux of 15.11-MeV \( \gamma \) rays relative to the flux of 4.44-MeV \( \gamma \) rays from the de-excitation of the corresponding states in \( ^{12}\text{C} \) is calculated for a number of assumed distributions of exciting particles. This flux ratio is shown to be a sensitive diagnostic of accelerated particle spectra. Other high-energy nuclear levels are not so isolated as the 15.11-MeV state and are not expected to be so strong. The spectrum of \( \gamma \) rays from the decay of \( \pi^0 \) is shown to be sensitive to the energy distribution of particles accelerated to energies greater than 100 MeV.
