This presentation covers the technical background of the subjects of dissemination as well as redissemination and fiber life. These subjects were defined in the overview presentation. Dissemination, as shown in figure 1, is the first release of the fiber and the drift of the fibers, or clumps, or fragments in the pollutant cloud downwind from the accident scene. Those fibers will of course deposit somewhere and there is a possibility that they are either stirred up by wind or traffic to be redisseminated. If they are not redisseminated, then they might be buried in the ground or destroyed. That's the subject of fiber life.

I want to treat first the dissemination portion of the problem and give you a basic introduction. I want to leave you with a qualitative idea of how the fibers are disseminated and some quantitative feel for the range and the amount of dissemination.

In figure 2 you see a typical accident scene. Above the aircraft accident we consider having a fire plume, which as long as
it has thermal energy also has buoyancy and therefore a vertical velocity. After a while it mixes with the ambient air and it will stabilize. After that we consider the next phenomenon which is the drift of the pollutant cloud downwind over industry, domestic areas, and possibly out to sea. The whole process is very strongly dependent on the weather. One of the first characteristics of a certain weather situation is the vertical temperature profile in the atmosphere, because mixing of aerosols occurs only in the convective band, i.e. below the inversion.

In this first case, in figure 3, which is typical of a nighttime situation, we have an inversion at about 200 m. So the mixing occurs over a relatively shallow layer. If there are any winds, they are typically very low, so that the cloud drifts slowly. This nighttime weather would be categorized as an E or F Pasquill-Gifford stability class. As you can see on the sketch below this first case, the moon is shining, and the plume is spreading at a relatively shallow angle that is characteristic of stable weather conditions. The spread angle is of the order of 10 degrees, sometimes even less.
In the second weather situation, called a neutral weather category, we have typically very high winds, typically it is overcast and the mixing depth is very much deeper, on the order of 400 meters. The sketch shows overcast weather and a spread angle of the plume cloud on the order of 20 degrees, somewhat larger than for the stable weather. In the third category, that's the weather we all like to have, and don't often get, it's the typically sunny weather, low winds, and Pasquill-Gifford category unstable A. If ever you see cumulus clouds in the sky, you know you have unstable weather, usually B sometimes A. The mixing layer is typically more like 1500 meters. The atmosphere is mixed over very great depths and of course, that means also that the pollutants are mixed over those depths. The sketch shows the sun shining and the plume spreading at an angle of about 40 degrees. When it encounters the inversion the plume will not penetrate that inversion because there is no vertical turbulence up there. It will stay below the inversion, or reflect.

Next I want to define the measures of pollution shown in figure 4. One thing that is of course important is the concentration of the pollutant, the number of particles over the volume, or volumetric density. Usually, more important than the
MEASURES OF POLLUTION

1. CONCENTRATION, \( C = \frac{\text{NUMBER OF PARTICLES}}{\text{VOLUME}} \)

2. EXPOSURE OR DOSAGE, \( E = \text{CONCENTRATION \times TIME} \)

\[ = \int C \, dt \]

3. DEPOSITION, \( D = \frac{\text{NUMBER OF PARTICLES}}{\text{AREA}} \)

concentration is the exposure, which is the concentration times the time of exposure, or the time integral of concentration. In some instances, the number of particles that get deposited on the ground, or the number of particles per unit area would be a suitable measure of pollution. Measure of pollution is not quite the same, of course, as the measure of potential damage. We have to measure the potential damage. We also need to know the area over which we get certain exposures. Therefore we plot an area-exposure diagram. For each exposure such as exposure E4, in figure 5, we calculate and plot the area A4, over which that level of exposure is exceeded. The integral \( \int E \, dA \) is a significant measure of potential damage. The others are just a measure of pollution. One important point, at this time you've seen this morning that the vulnerability or the damage is a continuous proportional function of exposure, so that even at extremely low values of exposure, you still have a very small probability of failure. Now if you have a very large area, at a given small exposure, the product of that large area and exposure contains a lot of equipment and may cause just as much damage as having exposure over a small area. That is peculiar to this situation which we have - a probability of damage continually defined as a function of exposure, whereas in other pollution problems we talk about a critical value below which we're safe, above which we're unsafe.
Many of you have seen the type of footprints that have been used in the studies of the last few years to show the range over which we can affect the countryside. Figure 6 is drawn basically to give a qualitative feel for how strong the exposure effects can be. In the top left hand figure, I've drawn an exposure profile where the outermost exposure profile represents about 5% of the maximum exposure in that area. For the weather condition which was an overcast weather or night, in other words, a stable weather situation, the exposure pattern is a very narrow streak, and it could extend the five percent level 100 kilometers from the accident scene. In the unstable, sunny weather, the dispersion is very much wider, the dilution of the pollution is much stronger so the 5% level is very much closer in. In this case I've shown it as about 50 kilometers but the area is roughly the same as in the previous case because the streak is now wider. Those cases are for single fibers with fall velocity of 0.02 meters per second. Let's look at the heavier particles. Looking at lint, which was characterized as being a group of fibers typically 20 or more, it has a fall velocity one order of magnitude larger, or 20 centimeters per second. Now, that would mean it would take approximately a half a minute to fall from the ceiling to the floor in this room, whereas a single fiber would take on the order of 300 seconds, or six minutes. Thus for the
lint, the 5% level might occur out at 10 kilometers in the overcast weather and at about half that distance in the strong sunshine with the wider exposure field.

**Figure 6**

Figure 7 lists the parameters controlling the dissemination patterns. The fire starts the dissemination problem, and is influenced by the amount of fuel, the burning rate, the pool size, and maybe some other factors, like the pool shape, or the number of individual pools of fuel. The exposure levels of course are controlled very strongly by the source, that is, how many fibers do we get out, what length fibers do we get out and what fragments do we get out? We want to characterize those by distribution of size and fall velocity. The weather strongly influences the dissemination pattern. The effect of the vertical stability conditions and mixing layer depths has been discussed. The wind velocity influences how far the material drifts down range in a given time, and fibers can be precipitated with rain or snow. Figure 8 shows the logic for two fire plume model types: empirical models and physical models. The first model is the empirical model which consists basically of the Briggs' equations. Those equations are based on observations of smoke stacks and provide reliable answers for the stabilization height and location.
PARAMETERS CONTROLLING DISSEMINATION PATTERNS

FIRE: AMOUNT OF FUEL
      BURNING RATE
      POOL SIZE

SOURCE: AMOUNT OF LOFTABLE DEBRIS
       SIZE AND FALL VELOCITY OF PARTICLES

WEATHER: CATEGORY: STABLE, NEUTRAL, UNSTABLE
       WIND VELOCITY
       MIXING LAYER DEPTH
       PRECIPITATION

Figure 7

OUTPUT:

STABILIZATION HEIGHT
CLOUD SIZE
CLOUD LOCATION

STATUS: UNDER DEVELOPMENT
REQUIRES VALIDATION TESTING

Figure 8
The growth of a fire plume is somewhat different from a smoke stack, so that an empirical expression was derived for the type of fire of interest. In most cases the fire plume will grow at an angle of approximately 40 degrees, as shown in Figure 9, so that the cloud location and stabilization height can be obtained from the Briggs equations, the cloud size from the 40 degree estimate. The second type of models are the physical models. Some work was done under contract to develop a model which takes the input conditions - fuel amount, burn rate, and weather - to obtain a physical representation of a fire including cloud height, size, location, flame temperature, flame velocity, flame chemistry, and the potential fiber burn up, which may be of importance. Some preliminary flame velocity data from this model are presented in figure 10 showing flame velocities up to about 15 meters per second. For the two fires shown here, a 7.5 meter pool and a 30 meter pool, you see that as a function of nondimensional radius from the center at a height 5 meters above the ground, both fires have about the same peak, but the little pool has already developed a more uniform plume shape. Another output from that type of model is the temperature distribution inside those fires, shown in figure 11. We see some results that were
Figure 10

VELOCITY PROFILE, HEIGHT 5 m

Figure 11

TEMPERATURE PROFILE, HEIGHT 5 m
surprising and that were referred to earlier in a question. You see for a small pool at the 5 meter height above the ground, the temperatures are relatively low - the peak temperatures are about 1500 Kelvin which is in the range of temperatures we have been talking about. But for the large pool, we have temperatures of approximately 2300 Kelvin or 2000 degrees centigrade - very high temperatures with a very great potential for burning up the fiber. In this fire the influx of oxygen around the base is so strong that stoichiometric conditions exist, and very good oxidation and very high temperatures result.

A typical analysis of the amount of graphite fibers consumed in a fire showed that a relatively small percentage of the fibers is lost (figure 12). Other cases like the high temperature fire of course would consume a larger percentage of fiber.

As the fire plume rises, mixes, and cools, it reaches a stabilization point. At that point the output conditions from the plume models are transferred as input conditions into the dissemination model. Normally the pollutant is assumed distributed in a Gaussian manner, either spherical for a short duration source or two-dimensional for a continuous plume. The Gaussian distribution has a minus R square exponent term so that we get the bell shaped distribution around the center of the cloud as shown in figure 13. That distribution shape and the size of the cloud go into the
dissemination models. Basically, there are two types of dissemination models, the Gaussian models and the particle-in-the-cell models. In the Gaussian models, we assume that this initial Gaussian cloud drifts downwind and grows so that the standard deviation (the sigma terms) keep growing in two or three directions as the cloud drifts downwind. If the cloud strikes the inversion level, as it does in figure 14, the material in the cloud is reflected back. Some fairly complex programming steps have to be taken to reflect the material back in the computations. There are several of these Gaussian models, such as the Tretheway and Cramer models, and of course, the EPA Turner models, which are being developed for pollution problems. The dispersion coefficient, namely, the angle at which the cloud spreads, has been determined empirically for the various Pasquill-Gifford stability classes, so that you have a 10 degree cone for the stable weather and you have a 40 degree cone for the unstable weather. They are somewhat difficult to adapt to complex terrains and wind profiles. The Gaussian models are very cheap to run; a single analysis on a large computer requires fractions of a second for any one dispersion case. We use them in various forms in our risk assessment contracts. The other model type, indicated in figure 15, the particle-in-a-cell model, takes little particles in a cell and by brute force solves the 3-D diffusion equations.

- Terrain, wind profile and other secondary details included in boundary conditions.
- Expensive to run.
- Necessary for specific case studies.

Figure 15
including of course the fall velocity of the particles. Depending on the required precision it is a very lengthy computation. The diffusion is based on the same input data as used for the Gaussian models. The diffusivities are back calculated from the smoke plume model. In those models it is easy to adapt to a terrain for a certain wind profile and any other secondary details. Now that is important, because sometimes a cloud drifts a hundred kilometers downwind over a long time including changes in wind speed and direction as well as changes in the inversion height. These models are extremely expensive to run on computers, but to do a specific test run such as tracking a specific accident, requires the use of those models to get the precise details of where the material went.

A parametric dissemination analysis was developed to get a quantitative feel for the size of the dissemination pattern. This analysis is shown in figure 16 in a nondimensionalized form where the distance away from the source is divided by the mixing height. The fall angle ($\beta$) is the fall velocity of the particle divided by the wind speed, ($N$) is the number of particles and ($\alpha$) is a horizontal spread angle in which all the material is contained uniformly. The exposure equation (shown) contains the source terms, proportional to the number of fibers and their fall velocity data, as an exponential term. The denominator has the weather factor term $UH^2\alpha$, which is the product of the inversion

**PARAMETRIC MODEL PREDICTIONS**

PARAMETERS:

\[
\begin{align*}
\zeta &= \frac{R}{H} \\
\beta &= \frac{v_s}{u} \\
N &= \text{NUMBER OF PARTICLES IN THE CLOUD} \\
\alpha &= \text{HORIZONTAL CLOUD SPREAD ANGLE}
\end{align*}
\]

DOSAGE EXPOSURE PROFILE:

\[
E = \frac{N}{uH^{2}\alpha} \times \frac{1}{\zeta} \times e^{-\beta\zeta}
\]

DEPOSITION PROFILE:

\[
D = N \left[ 1 - e^{\beta\zeta} \right]
\]

Figure 16
height squares, the spread angle, and the wind velocity. Such is the influence of the weather on the exposure pattern.

The second equation is for the deposition profile. Out to the nondimensional distance $\rho$ you have a deposition fraction given by that equation. The weather factor, $UH^2\alpha$, as listed in figure 17, in the stable weather is about $3 \times 10^4$; in neutral weather, $5 \times 10^5$; in unstable weather, $4 \times 10^6$, indicating that the exposures decreased by an order of magnitude everytime you go towards the sunny weather. Sunny weather gives you 1/100th of the local exposure values of the stable weather - the nighttime conditions.

Figure 18 represents an almost scaled drawing of the dissemination pattern. Let's take single fibers with a 2 centimeter per second fall velocity and the wind at 2 meters per second and a mixing depth of 1000 meters. Only 60% of the fibers are deposited within the first 100 kilometers of the source; the others are still airborne. To drift down 100 kilometers, the cloud takes 14 hours. In that time of course, weather is going to change. You're not likely to have 100 kilometers of one weather system and even if you do, its going to change in 14 hours. Even if you were to have that stability, 40% of the particles would still be airborne, covering a wide sector of the countryside. For a case like that we can calculate the area coverage for the simple model. Once we have exposure,
SCALE OF DISSEMINATION

FOR SINGLE FIBERS \( v_s = 0.02 \text{ m/s} \)

IN A WIND \( u = 2 \text{ m/s} \)

WITH A MIXING DEPTH \( h = 1000 \text{ m} \)

60% OF FIBERS ARE DEPOSITED WITHIN 100 KM OF THE SOURCE

Figure 18

We can calculate the area over which that exposure occurred. We have three curves, the stable, the neutral and the unstable weather situation plotted in figure 19. You see that the stable weather situation has the high values of exposure but over a small area, whereas the unstable weather covers the extremely large areas with the lower values of exposure. Surprisingly, the total integral, which we're very interested in for vulnerability calculations, is the same for all three. We can take those data and plot the exposure and the area in nondimensional form - exposure times the weather factor, divided by \( N \), versus a nondimensional area term. Some Tretheway-Cramer calculations for three situations - unstable, neutral and stable-fell just about precisely on that predicted relationship for single fibers. Their prediction for lint fell just about precisely on our predictions for lint as shown on figure 20. This parametric representation for small fall velocity says that the exposure falls off as the reciprocal of the distance. This guides our thinking on how the exposure profiles vary.

We've got some interesting field data for some heavy particles in the fire test at China Lake. We actually recorded the coordinates of all the strips that we found as shown in figure 21. For the purpose of this exercise, I categorized them within certain sections of range. Figure 22 shows the number of strips...
AREA COVERAGE

LINT

NONDIMENSIONAL EXPOSURE \( E \times \frac{uH^2\alpha}{N} \)

Figure 20
within each interval, as well as the cumulative deposition within each interval. Assuming a wind velocity of about 5 m/s, a fall velocity of about 5 m/s (because they were very heavy fragments), an average mixing depth at that time of 700 meters, and 130 particles, we can plot both the data and the equation for the deposition. At least in this case we see in figure 23 that the exponential profile of total deposition as a function of range is approximately valid.

Last, I want to calculate the pollution effects for a possible scenario. Assume a source of 1000 kilograms - a metric ton of composites on an airplane. If we were to destroy that airplane in a fire, we could assume 5% would be released as singles, 5% would be lint, 20% airborne fragments, and 70% residue on the ground, as listed in figure 24. From the mass of any one of those fragments, we know the number of particles for each one of those fragments per kilogram of material, we know the total particles of each category and we know their fall velocities. Now we want to calculate the exposure patterns from that source. First of all let us take the data for the singles, and we find that in stable weather, an area of approximately 1 city block will be covered at an exposure of about $10^5$ particles, as shown in figure 25. Whereas in unstable weather, that same area would be covered at an exposure of about $10^4$. In the unstable case, for an exposure of $10^4$, an area equivalent to a full state would be covered, whereas in the stable case, for that value of exposure, an area of

*Figure 25*
a big city could be covered. That is the range of exposure from this metric ton release of composite. Let's look now at the other fractions in figure 26, and instead of calculating what exposure levels occur, since we don't know vulnerability in terms of exposure for those fractions, I plotted the deposition density. For the lint, we have $5 \times 10^7$ particles released. In the stable case, at about 1 kilometer out, we have 50 particles per square meter deposition density, and in the unstable case approximately an order of magnitude less. For the fragments at 500 meters out we have about 0.4 particles per square meter, and in the unstable case, again, significantly less. Those data are not used in the risk assessment because we haven't qualified the vulnerability of equipment to that type of particle.

In summary, as listed in figure 27, we know the following about dissemination. We have the simple fire plume models available. The differences between all of them affect only the short range immediately around the fire. We have the complex fire plume models under development, they will be most useful to use in determining the oxidation potential of the fibers. We have cloud dissemination models available; we have the simple Gaussian models, which we're using in the very many repetitive runs that we need to do for a risk assessment, and we have the complex models which we could use if we ever needed them for specific tracing of an event. We have the parametric analysis which gives us a little more quantitative insight into the
SUMMARY FOR DISSEMINATION MODELS

- SIMPLE PLUME MODELS AVAILABLE
  - DIFFERENCES AFFECT SHORT RANGE ONLY

- CLOUD DISSEMINATION MODELS AVAILABLE
  - SIMPLE, SUITABLE FOR REPETITIVE APPLICATIONS

- PARAMETRIC ANALYSIS SHOWS THAT AREA COVERAGE IS INSENSITIVE TO UNCERTAINTIES IN MODELS

- SUFFICIENT TEST DATA AVAILABLE TO VALIDATE DISSEMINATION MODELS

Figure 27

interrelations between the very many parameters involved. But it also shows that the total area coverage, which we're using as a measure of our damage potential, is rather insensitive to a lot of parameters that go into the fire plume model and into the dissemination model. We now feel that we have sufficient test data to validate our dissemination models to the levels of accuracy that we required for this study.

I will talk about fiber life and redissemination as outlined in figure 28. I want to talk about outdoor testing, the program direction that we have in mind, and a brief summary. In a study done in the desert in which we checked on the redissemination of some fibers that had been deposited there, we could get a measure of the significance of the redissemination of the single fibers. The data that we plot in figure 29 are the vertical deposition, which means the tuna can catch, over a 24 hour period, as a function of the time after the deposition, since June 75 to the present. After a very high initial peak the deposition falls to very low levels. Integration shows that by now, 1% of that source has been redissemination. The other data in figure 30 show that the fibers initially had a 8 mm mean length but as time went on the type of fibers collected became shorter and shorter, so that by now, three years after the event, the average fiber length
REDISSEMINATION

- Desert study shows some redissemination off hard-pan surface

- Fiber length decreases with time
- Redissemination from vegetated land insignificant
- Subject under continued study

Figure 28

Vertical deposition of fibers as a function of time

Figure 29
collected is approximately 1 millimeter. The residual fibers are caked into the desert crust. Some of them stick out, and the only time any of those fibers are released is when saltating particles rolling along the ground strike pieces of graphite off the clumps that are lying there. That's the mode that we currently feel is in operation out there, and the reason for the shorter fibers. The conclusion is, that the dissemination rate decreases with time, and the fiber lengths decrease with time, or to be more precise, the spectrum of size has its maximum at a shorter length. The desert country out there can be classified as hard pan surface which has a very short roughness length that makes it possible for the singles to be picked up. In a vegetated country, like even short grass, agricultural lands, or forests, it would be impossible to redisseminate singles back out of those depths because the boundary layer is so thick and laminar. Therefore, we feel that we won't get much redissemination from anything except a hard surface. That subject of course is under contained study.

Let me show you on figure 31 the road map for what we have in mind. This is the problem for single fibers. Starting with the deposition, they can fall into water, vegetation, or they can fall on hard top. On the first two, those fibers must be considered as dead, the resuspension rates are very very small. From
the hard top, which might be typical of a city area, concrete, asphalt, roofs, much of it could be washed down into the drainage system of a large city. The rest might be available for redissemination. But on the whole, the amount available for redissemination represents a small fraction from a very small area. Let's look at the larger fragments in figure 32, where we just calculated a deposition density. Those fibers could again be deposited in water, where they would be immediately lost. In vegetation, with deep vegetation forests, they would be lost. The big particles however are going to sit on top of shallow vegetation, like lawns. They could essentially be fragmented by wind action or other disturbances. They could land on the hard top where some could be lost to washdown. We could clean up the area and get rid of some of them once and for all. Traffic could fragment those remaining particles providing a source of single particles. Now that would remain the main study issue, because the large clumps and fragments contain most of the mass of the debris and could act as a substantial source of singles. However, again you're looking at the possibility of resuspending from only a very small area.

In conclusion, we need to continue working this issue of redissemination, but are relatively confident with the other
models of dissemination and the fire plume models. We are working on advanced models to get oxidation state.

Question: How did you test the parametric model?

Response: I took the strip data set from the spoiler burn test and analyzed the deposition, and found that it was an exponential distribution.
