5.0 MODEL VERIFICATION

In order to establish the validity of the EMA model, comparisons are made between results obtained from lab tests on the actual EMA and those from equivalent computer simulations. The computer program has several run options as described earlier in Section 4.5, for this reason, the following verification schedule will be followed:

1. Verification of the Power Conditioner and Machine Model
   - Motoring
   - Regeneration
   - Plugging

2. Verification of the Fourteenth Order EMA Model
3. Verification of the Tenth Order EMA Model

Table (5.0-1) catalogs the various computer runs which are used in this verification procedure. The results of these runs are presented in the twelve appendices: A.1-A.3, B.1, C.1-C.3, D.1, E.1-E.4. In terms of the aforementioned verification program, these appendices are organized as follows:

1. Power Conditioner and Machine Model
   - Motoring: Appendices A.1, A.2, and A.3
   - Regeneration: Appendix B.1
   - Plugging: Appendices C.1, C.2, and C.3

2. Fourteenth Order EMA Model: Appendix D.1

The tests on the actual hardware were performed by Delco Electronics and are described in References (2), (3), and (4).

A summary of each computer run is given on the first page of each of the twelve appendices. The results of these computer simu-

lations are plotted by a CalComp pen type plotter. Tables 5.0-2 and 5.0-3 contain listings and descriptions of the CalComp plots. Figures (A.1-1), (A.2-1), (A.3-1), (B.1-1), (C.1-1), (C.2-1), (C.3-1), (D.1-1) (E.1-1), (E.2-1), (E.3-1), and (E.4-1) give the status of the logic signals versus time for each of the twelve computer runs. These (5.0-4) signals are defined in Table (5.0-4). With these logical variables the reader can easily follow the status of each solid state power conditioner element as time progresses.

A few conventions must be established to facilitate the comparison and discussion which will follow. It will be agreed upon, in the language of this report, that the time origin in all the waveforms included here is at the farthest left hand side of the figures. Also, positive time is measured to the right hand side of the origin. The edge of a positive half-waveform closer to the time origin will be referred to as the "leading edge". On the other hand, the edge of a positive half-waveform farther from the time origin will be referred to as the "trailing edge". The waveform for various currents and voltages which are obtained from computer simulations will be referred to by the abbreviation CSWF. It should be pointed out that various CSWFs and their corresponding oscillogram counterparts have been obtained under slightly different operating conditions (speed, current command, etc.). Also it must be made clear that these investigators had no control over the experimental test procedures and conditions, since they were performed at a different facility.

5.1 VERIFICATION OF THE POWER CONDITIONER AND MACHINE MODEL

The power conditioner and machine model is verified by comparisons of simulation runs with actual oscillograms obtained from tests performed on the EMA. These comparisons are made for each of the three modes, as follows:

- Motoring: 5000 rpm ICMD = 31.5
- Regeneration: 5101 rpm ICMD = -38
- Plugging: 240 rpm ICMD = 32

The input data used for the power conditioner and machine is given in Table (5.1-1).

Computer simulations were obtained for the three basic modes of operation for the brushless DC machine-power conditioner package. The first mode is the forward motoring case at a rotor speed of 5000 r.p.m. The corresponding current and voltage waveforms through and across the numerous elements of the network for various commutation angles are given in Appendices A.1, A.2, and A.3, respectively. The second mode given here, is the generator (regenerative braking) case at a rotor speed of 5101 r.p.m. The corresponding current and voltage waveforms are given in Appendix B.1. The third mode studied is the forward braking case at a rotor speed of 240 r.p.m. The various waveforms obtained during this mode are displayed in Appendices C.1, C.2, and C.3. For the sake of convenience and comparison purposes some of the figures given in these appendices are repeated here with their corresponding experimentally obtained counterparts.

Figure (5.1-1) shows experimentally obtained oscillograms of the machine phase currents at a speed of 5000 r.p.m. and with a comm-

UNITS: Ohms, Henries, Farads, and Volts.
utation advance of 30 electrical degrees. The corresponding CSWF of the currents through phase A for commutation advance angles of 30, 22, and 38 electrical degrees are shown in Figures (5.1-3), (5.1-4), and (5.1-5). Figure (5.1-2) shows the spatial relationship between the output AA of the RPS for phase A and the command to inject current into phase A, Q(1), for the chosen commutation angles. Examination of the current waveforms reveals the same characteristic over-shoot and under-shoot at the leading and trailing edges of the oscillogram and the CSWF. The positive peaks of the current oscillograms shown in Figure (5.1-1) are indicated by an (X) on the corresponding CSWF, Figure (5.1-3). Notice the excellent agreement between the measured and computed current peaks. The transients in Figure (5.1-3) may appear exaggerated in comparison with Figure (5.1-1), but this is due to the "horizontal squeeze" and "vertical stretch" of the CSWF caused by the horizontal and vertical scaling of the plot. Both the oscillogram and the CSWF display the same chopper frequency of nine peaks per half cycle. Notice also the two slope current transient present in both cases in the middle of the positive and negative current cycle. Figures (5.1-4) and (5.1-5) demonstrate the effects of varying the commutation angle on the nature of the phase currents. This commutation angle also has a great effect on the electromagnetic torque of the machine as shown in Figures (A.1-1), (A.3-1), and (A.2-1), respectively.

The lower trace in Figure (5.1-6) depicts the oscillogram of the current through one of the transistor-diode switches in the six legged inverter-converter bridge leading to the machine phases. A corresponding CSWF is given in Figure (5.1-7). Excellent correlation
between the various ripples and pulses in the oscillogram and the CSWF are self evident upon examining these figures. Time congruence between the occurrence of the various ripples and pulses is also evident in these figures.

Figure (5.1-8) depicts the oscillogram of the main DC line current for a motoring mode. Notice the current dips which are occurring at regular intervals. The almost identical ripple and dip pattern is also evident in the CSWF given here in Figure (5.1-9). Again the agreement between the numerical and test results is excellent.

Figure (5.1-10) gives the phase current for the generating (or regenerative braking) mode at a rotor speed of 5101 r.p.m., Figure (5.1-11) depicts the corresponding CSWF of one of the three phase currents at a constant rotor speed of 5101. Again agreement between the oscillogram and the CSWF is excellent.

The last oscillogram, Figure (5.1-12) was made while the machine-power conditioner was operating in the braking mode at a speed of 240 r.p.m. The upper trace of this oscillogram shows a typical phase current for this mode of operation. The corresponding CSWF is given in Figure (5.1-13). The lower trace of Figure (5.1-12) shows the waveform of the current through one of the transistor switches connected to the permanent magnet machine. The corresponding CSWF is given in Figure (5.1-17). The CSWF shown in Figure (5.1-13) was obtained by using a reduced emf waveform, see Reference (15). The CSWFs of Figures (5.1-14), (5.1-15), and (5.1-16) where obtained using the magnetized and demagnetized back emfs described earlier in Section 2.4. The reduced emfs are better in this case because

the large circulating phase currents result in the saturation of the stator teeth and yoke thereby increasing the mmf drop across the stator and hence reduced back emfs. The inclusion of this nonlinear stator reluctance in the back emf routine can be accomplished by a Finite Element analysis of the two dimensional nonlinear magnetic fields which govern the electromagnetic behavior of this machine.

5.2 VERIFICATION OF THE TENTH AND FOURTEENTH ORDER EMA MODELS

The overall EMA was modeled using both a detailed and a simplified model of the power conditioner and machine network. Delco electronics, References (2), (3), and (4), performed a series of step responses on the actual hardware using four flap position commands of 1.1, 1.65, 2.2 and 2.75 flap degrees. The results of step responses are tabulated in table (5.2-1). This table contains the times it took the flap to reach the commanded flap positions for the first time. The maximum overshoot is also given. Close examination of this data reveals the excellent agreement between experimental and simulation results.

The results of the 14th order EMA model are given in Appendix (D.1). Figures (D.1-1) through (D.1-14) display some typical waveforms produced by the EMA in response to a step position command. Figure (D.1-1) displays the status of the various EMA logic signals versus time. The extreme variations in rotor speed during such a maneuver is illustrated by the changing width of the RPS outputs (AA, BB, and CC). Since each RPS pulse corresponds to 45 degrees of rotor displacement, the narrow RPS pulses occur at high rotor speeds

and vice versa. The machine torque during the step response is given in Figure (D.1-2). The rapid fluctuations in the torque are due to the sawtooth component of the machine phase currents which is produced by chopper. Notice that as the machine velocity reaches its maximum (at approximately 0.15 sec) value, the average machine torque is significantly reduced. This is due to the increasing machine back emfs with increasing speed. This torque reduction at higher speeds results in velocity saturation which is graphically illustrated in Figure (5.2-1) (Figure (D.1-10)) and in Figure (5.2-2) which shows the corresponding observed velocity, Reference (4).

The response of the flap to the step input is given in Figure (5.2-3). This waveform agrees with the oscillogram of the actual response given in Figure (5.2-4). Because of the linear relationship between machine current, IM, and torque, TM, the machine current, Figure (D.1-4) is very similar to Figure (D.1-2).

The computed velocity error given in Figure (D.1-5) shows how the velocity error approaches zero in time. The position error also approaches zero towards the end of the step response as expected, see Figure (D.1-14).

The filtered current command IMC is displayed in Figure (D.1-6). The rectangular notch at t = .24 seconds is due to the lower current limit during plugging. The rate and magnitude limited current ICMD1/5 is shown in Figure (5.2-5) as well as in Figure (D.1-7). This compares favorably with the actual current command waveform given in Figure (5.2-6).

The action of the current rate limiter is displayed in Figure
(D.1-9). The reaction torque, TACT, given in Figure (D.1-11) shows the spring loading effect due to the nonzero value of the final flap position.

In addition to these runs, the step response to the various position commands of Table (5.2-1) have been determined using a simpler 10th order EMA model. Comparison of these results to test results demonstrates that the simpler model does an excellent job of predicting the step response.

5.3 CONCLUSIONS AND RECOMMENDATIONS

A comparison was made between the experimental test results, Reference (2), and the numerical results presented in Appendices (A) through (E). In all cases excellent agreement was found between the waveforms obtained from the actual machine-power conditioner package and those obtained from the mathematical (numerical) model. This close agreement between the behavior of the actual hardware and the mathematical model strongly suggests that the underlying assumptions and simplifications used in the development of this model are valid and sound.

Future improvements in this model can include the following endeavors:

1. The development of a rigorous magnetic field analysis model for the determination of airgap flux density waveforms under load and no load. This model would constitute the heart of a program for the calculation of the machine back emfs in the machine-power conditioner network, as well as the calculation of the electromagnetic dynamic

torque. Such a package would allow the calculation of more accurate motor leakage inductances, which are necessary for accurate commutation studies. Such a model can also be used for the determination of better magnet-airgap configurations for optimum torque and dynamic characteristics.

2. Increasing the order of the mathematical model in order to include the effects of the various capacitors and inductors which have been neglected in the present model.

3. The incorporation of items (1) and (2) mentioned above into an overall EMA design optimization program. Such a program would determine the optimum system parameters given a set of system constraints. This type of capability would be useful in tailoring the system to a given application.
