INTRODUCTION:

Our research efforts during this past year of NASA sponsorship have concentrated on identifying atoms or molecules that are attractive as potential nuclear-pumped lasers. These studies have led to the examination of the iodine-monofluoride (IF\textsuperscript{*}) molecule. Specifically, as a direct result of NASA funding, the following accomplishments have been realized in the past year:

1) The blue-green emission spectrum of IF\textsuperscript{*} in e-beam excited Ar, NF\textsubscript{3} and CF\textsubscript{3}I mixtures has been observed and assigned to the E \rightarrow A\textsuperscript{3}\Pi\textsubscript{1} transition.

2) From fluorescence measurements, the radiative lifetime of the excited molecule has been estimated to be \( \approx 15 \) ns.

3) The IF\textsuperscript{*} kinetic formation chain has been determined to be: \( \text{Ar}^{*} \rightarrow \text{Ar}_{2}^{*} \rightarrow \text{I}^{*} \rightarrow \text{IF}^{*} \), where \* indicates an electronically excited state of the atom or molecule indicated

4) The rate constants for quenching of I\textsuperscript{*} and ICI\textsuperscript{*} by various atoms and molecules (including UF\textsubscript{6}) have been measured.

Simply stated, IF appears to be a very attractive choice for a laser to be pumped by the gaseous core reactor. For instance, the \( E \rightarrow A\textsuperscript{3}\Pi\textsubscript{1} \) band of IF lies in the blue-green and, therefore, UF\textsubscript{6} ground state absorption will be negligible. Also, quenching of IF\textsuperscript{*} by UF\textsubscript{6} is sufficiently small that a potential IF laser would be compatible with \( \approx 1-10 \) Torr of UF\textsubscript{6}. Also, since IF contains one fluorine atom, then UF\textsubscript{6} can be used to form the laser's upper state.
Finally, the highly structured nature of the IF\(^*\) blue-green emission band, the short (\(\sim 15\) ns) IF\(^*\) radiative lifetime and the Franck-Condon shift between the IF E and \(A^3\Pi_1\) states all indicate that the small signal optical gain from IF\(^*\) should be large.

In the last two months, a research group at Garching has succeeded in obtaining stimulated emission from IF. Lasing occurs at \(\lambda = 491\) nm. It is our intention of continuing the study of IF\(^*\) and, in particular: 1) to measure the pump power threshold for the laser and 2) determine the efficiency of an IF\(^*\) oscillator or the extraction efficiency of a dye-laser saturated IF\(^*\) amplifier.

The experimental results obtained during this past year are presently being written up for publication. However, the highlights of this experimental effort are summarized in the attached paper which has been submitted for publication.
IODINE-MONOFLUORIDE (IF) EMISSION SPECTRUM AND FORMATION KINETICS IN ELECTRON BEAM PRODUCED PLASMAS*

ABSTRACT

Intense blue-green fluorescence from a structured band centered at $\lambda \sim 484$ nm has been observed from Ar, CF$_3$I and NF$_3$ gas mixtures ($T = 300^\circ$K) excited by a $\sim 3$ ns FWHM electron beam. This emission is tentatively assigned to the $E \rightarrow A^3\pi_1$ transition of the iodine-monofluoride (IF) molecule. From the temporal behavior of the IF$^*$ and I$_2$ (342 nm) emission, it has been determined that the IF(E) level is formed primarily by excitation transfer from I$^*$ ($^4P$) states. The fluorescence efficiency of the IF(E $\rightarrow$ A) band and the IF$^*$ (E) state radiative lifetime have been estimated to be $\sim 6\%$ (in 99.83% Ar/.13% CF$_3$I/.04% NF$_3$ mixtures, $P_{\text{TOTAL}} \sim 2300$ Torr) and $\sim 15$ ns, respectively. The emission band structure, the short IF(E) radiative lifetime and the Franck-Condon shift between the E and A states suggest that IF$^*$ is an attractive candidate for a blue-green laser.

*Work supported in part by the NASA Langley Research Center under Contract No. NSG 1609.
The spectroscopic properties of the diatomic halogen molecules have been studied extensively for several decades and since 1975, stimulated emission has been obtained from each member of this molecular family (I₂, Br₂, C₂ and F₂).¹

In contrast, although numerous studies of the low-lying A²π₁ and B²π₀ states of the interhalogen molecules (BrF, IC₂, etc.) have been conducted,²⁻⁵ for many of these molecules little detailed information regarding higher excited states is available. Consequently, only recently have the interhalogens received attention as UV and visible laser candidates.

Huestis and co-workers⁶ have observed strong fluorescence bands (from electron beam (e-beam) excited Ar and IC₂ or IBr gas mixtures) at 385 and 430 nm which were attributed to ionic to covalent transitions of IBr and IC₂, respectively. Optical gain was observed on the blue IC₂ band but, due to ground state IC₂ absorption,⁶,⁷ oscillation was not obtained. Diegelmann et al.⁸ subsequently reported lasing at 285 nm from the C₂F molecule when formed in e-beam excited Ne/F₂/C₂ gas mixtures. However, the identity of the states responsible for these e-beam pumped IC₂, IBr or C₂F emission bands remains unclear.

The observation of intense blue-green spontaneous emission from e-beam excited Ar/CF₃I/NF₃ gas mixtures is described here. To our knowledge, this emission band, which peaks near λ ~ 484 nm, has not been reported previously⁹⁻¹¹ and is tentatively assigned to the E ⟷ A²π₁ transition of the iodine-monofluoride (IF) molecule. Both CF₃I and CH₃I have been utilized as iodine donors to minimize absorption in the 450-500 nm spectral region.¹²⁻¹⁴

The experimental apparatus used in these studies consisted simply
of a Febetron 706 e-beam generator, an optical cell and gas handling equipment and a detection system. After traversing a \( \sim 1 \) cm thick atmospheric drift region, an intense (\( \sim 1 \) kA/cm\(^2\)), \( \sim 3 \) ns FWHM beam of 600 keV electrons irradiated a mixture of Ar, CF\(_3\)I and NF\(_3\) contained in a stainless-steel cell. The emission from the excited gases was viewed transverse to the e-beam axis by a 0.6 m spectrograph (in first order) and Polaroid Type 57 (or Kodak Tri-X) film and by a biplanar photodiode with an S-20 surface. Bandpass or calibrated neutral density filters were placed in the optical path to prevent saturation of the photodiode and to isolate the desired spectral region. Research grade rare gases and technical grade CF\(_3\)I, NF\(_3\) and F\(_2\) (as supplied by the manufacturer) were used in these experiments. Passivation of the e-beam cell and gas handling system was accomplished by allowing \( \sim 50 \) Torr of F\(_2\) to stand in the cell for \( \sim 0.5 \) h. Finally, calibration of the observed spectra was afforded by a Hg pen lamp.

Upon exciting 2000-4000 Torr Ar, 3 Torr CF\(_3\)I and 1 Torr NF\(_3\) gas mixtures with the e-beam, the intense blue-green emission band shown in Fig. 1 was observed. Vibrational structure in the band is evident and maximum emission occurs for \( \lambda \sim 484 \) nm but the fluorescence extends to wavelengths < 430 nm. When either the NF\(_3\) or CF\(_3\)I was removed from the gas mixture, the band of Fig. 1 vanished. Also, the same spectrum was recorded (although with diminished intensity) if NF\(_3\) was replaced by F\(_2\) or if He or Ne was used as the mixture diluent. Therefore, this blue-green band is attributed to the diatomic iodine-monofluoride molecule (IF) and is the longest wavelength diatomic halogen emission yet observed for relativistic electron beam excita-
tion. Table I shows that the ~ 484 nm peak wavelength of the IF spectrum is consistent with the known wavelengths\(^3,6\) of the other iodine-monohalide emission bands (e-beam produced).

In order to identify the electronic states responsible for the 484 nm emission, an analysis of the ICl and IBr spectra (from e-beam irradiated Ar, CF\(_3\)I and Cl\(_2\) or IBr gas mixtures) was undertaken. This approach was adopted simply because the excited states of ICl and IBr are better known than those of IF. For ICl, a close coincidence was found to exist between the measured emission spectrum and \(v' = 0,1 + v'' = 3-6\) transitions of the ICl (E \(\rightarrow\) A\(^3\pi_1\)) band, as calculated from the spectroscopic constants and vibrational transition assignments given by Rosen.\(^3\) The peak ICl emission at 433 nm was identified as the \((0,4)\) transition of the E \(\rightarrow\) A\(^3\pi_1\) band. A similar analysis of the e-beam excited IBr band led to an analogous conclusion: that the band peak at \(\lambda \sim 356\) nm corresponds to the \((0,4)\) transition of the D \(\rightarrow\) A\(^3\sigma_1\) band.\(^15\) Neither the ICl nor IBr spectra could be explained by assuming \(B^3\pi_0^+\) to be the lower energy state,\(^8\) a result which may bear on attempts to identify the origin of the 342 nm band of I\(_2\).\(^16,17\)

Preliminary analysis\(^18\) of the wavelength separation between the local maxima of the IF* emission spectrum (Fig. 1) suggests that \(\omega_e\) (upper level) \(\sim 250\) cm\(^{-1}\). Hence if the emission band peak at \(\lambda \sim 484\) nm is assigned to the E \(\rightarrow\) A \((0,4)\) transition (consistent with the ICl and IBr spectra), then \(T_e(E) \sim 37967\) cm\(^{-1}\). Table I shows that these rough estimates of \(T_e\) and \(\omega_e\) are in agreement with the trends established by I\(_2\), IBr and ICl. Moreover, if \(\omega_e\) and \(T_e\) of the E state are taken to be those estimated here, then the vibrational lines in
the IF* spectrum apparently originate from the $v' = 0,1$ levels of the E state and terminate on $v'' = 3-6$ of the $\text{A}^3\Sigma_1$ level.

In addition to the IF band, the only emission detected (from the Ar/CF$_3$I/NF$_3$ plasmas) between 250 and 650 nm was due to I$_2$* (342 nm). So, in order to investigate the formation kinetics of the IF* molecule, the temporal behavior of both the I$_2$* and IF* fluorescence was recorded using bandpass filters (I$_2$*: $T_{max} = 18\%$ at $\lambda_0 = 352$ nm, $\Delta\lambda = 12$ nm FWHM; IF*: $T_{max} = 70\%$ at $\lambda_0 = 495$ nm, $\Delta\lambda = 38$ nm FWHM).

Over a wide range of gas mixture compositions, the time decay of IF* and I$_2$* waveforms (for an example, see Fig. 2) was found to be identical to within experimental error. This suggests that these excited molecules are fed by a common precursor. A similar conclusion was reached in ref. 6 from experiments involving Ar/ICl plasmas.

Partial energy level diagrams for Ar, I, I$_2$ and IF are illustrated in Fig. 3. The I$_2$ states were redrawn from refs. 16 and 19 and the IF (X and A) levels were taken from the paper by Birks, Gabelnick and Johnston. The E state of IF is included simply to indicate its position relative to the I$_2$* (1432, $\text{A}^3\Sigma_2$) state but its equilibrium radius is probably slightly larger than shown in the Figure. Clearly, at least one of the I* ($^4\text{P}$) levels has sufficient energy to simultaneously break either the CF$_3$-I or NF$_2$-F bonds (2.32 and 2.52 eV, respectively) and populate low vibrational levels of I$_2$* or IF*.

Consequently, the kinetic scheme for IF* production is expected to be analogous to that proposed by Huestis et al for ICl. That is:
\begin{align}
\text{Ar}^* (\text{or Ar}_{2}^*) + \text{CF}_3\text{I} & \rightarrow \text{I}^* (4P) + \text{CF}_3 \ \ (1) \\
\text{and} & \\
\text{I}^* (4P) + & \\
\left\{ \begin{array}{c}
\text{NF}_3 \rightarrow \text{IF}^* (E) + \text{NF}_2 \\
\text{CF}_3\text{I} \rightarrow \text{I}_2^* (1432, 3\pi_2^g) + \text{CF}_3,
\end{array} \right. \ (2, 3)
\end{align}

where Ar* represents one of the low-lying Ar (3P) states and Ar_{2}^* is the metastable 3 I_u^+ excimer state.

Figure 4 shows the dependence of the time and wavelength integrated IF* fluorescence on the argon partial pressure for Ar, 2 Torr CF_3I and 1 Torr NF_3 gas mixtures. Initially, the integrated spontaneous emission increases as \( \sim t^{4/3} \), which suggests that Ar_{2}^* may be primarily responsible for I* formation in Eqn. (1). Above \( \sim 2300 \) Torr, the IF* fluorescence levels off due to increased Ar quenching of the molecule. Here, it should be noted that the internal energy of the Ar_{2}^* (3E) molecule is \( \lesssim 1000 \) cm\(^{-1}\) in excess of that required to break the CF_3-I bond and subsequently excite I to the 6s4P_{1/2} or 3/2 levels. However, Ar* (3P) atoms are capable of populating I* states \( \sim 3 \times 10^4 \) cm\(^{-1}\) above the 4P levels. Also, the Ar_{2}^* excimer formation process, Ar* (3P) + 2 Ar + Ar_{2}^* (3E) + Ar, competes with Eqn. (1) for the available Ar* (3P) atoms. Taking the Ar_{2}^* formation rate\(^{20}\) to be \( 1.7 \times 10^{-32} \) cm\(^6\)-s\(^{-1}\) \cdot [\text{Ar}]^2 \) and letting \( k_1 = 4.7 \times 10^{-10} \) cm\(^3\)-s\(^{-1}\)^{21} then for 3 Torr CF_3I and \( p_{\text{Ar}} > 1700 \) Torr, Ar_{2}^* formation is the dominant Ar* (3P) loss mechanism. The apparent conclusion, then, is that for the high Ar pressure gas mixtures characteristic of these experiments, the Ar_{2}^* molecule, rather than an Ar* (3P) atom, is the imme-
diate precursor to the I* (*p) state.

From the single exponential decay of the IF* waveforms from low pressure ($P_{\text{TOTA}} \leq 10 \text{ Torr}$) CF$_3$I/NF$_3$ gas mixtures, the IF* (E) state radiative lifetime has been estimated to be $\sim 15 \text{ ns}$. This result is consistent with the $\sim 7 \text{ ns}$ lifetime for the upper state of the I$_2$ 342 nm band. Therefore, the waveforms shown in Fig. 3 (for Ar, CF$_3$I and NF$_3$ mixtures) reflect the quenching of I* by CF$_3$I or NF$_3$. Measurements of the rate constants for collisional quenching of I* by various atoms and molecules and the IF* radiative lifetime will be described elsewhere.

Finally, by comparing the time-integrated IF* blue-green fluorescence to the N$_2$ (C + B) emission from Ar/5% N$_2$ gas mixtures, the fluorescence efficiency of the IF* (E $\rightarrow$ A$^3\pi_1$) band in e-beam produced 2300 Torr Ar/3 Torr CF$_3$I/1 Torr NF$_3$ mixtures was found to be $\sim 6\%$. Also, measurements of the branching ratio for IF* formation by quenching of I* (BR $\equiv \int \text{IF}^*(\lambda, t)d\lambda dt/ \int (\text{IF}^* + \text{I}_2^*)d\lambda dt$) in 2300 Torr Ar, PCF$_3$I, 1 Torr NF$_3$ gas mixtures revealed that $25\% \leq \text{BR} \leq 44\%$ for $\lambda \geq 1$ Torr.

In summary, strong blue-green fluorescence has been observed from electron beam excited Ar, CF$_3$I and NF$_3$ gas mixtures. This emission has been tentatively assigned to the E $\rightarrow$ A$^3\pi_1$ transition of the IF molecule and is likely the same transition that is responsible for the 385 and 430 nm bands of IBr and ICI, respectively. The emission spectrum and short radiative lifetime of IF* and the Franck-Condon shift between the E and A states make the molecule attractive as a potential laser. Also, none of the ground or excited state species that are known to be present in Ar/CF$_3$I/NF$_3$ plasmas absorb strongly in
the 480-500 nm spectral region. Since it would likely operate at room temperature, an IF blue-green oscillator would represent an improvement over the HgBr laser which requires operating temperatures in excess of 100°C. Consequently, experiments to obtain lasing from this molecule using both e-beam and discharge pumping are in progress.

The authors thank R. Dixon and Dr. R. W. Waynant of NRL for the use of a microdensitometer. Also, discussions with Prof. J. Tellinghuisen of Vanderbilt University regarding the IF spectrum are gratefully acknowledged.
