INTRODUCTION

Interest in surface cooling, boundary layer control and mixing process has promoted research in film cooling and blowing over a flat plate. For the film cooling application, normal injection, tangential slot injection, and injection through inclined holes have been the subjects of theoretical and experimental investigations to predict the film cooling effectiveness, \( \eta = (T_w - T_m)/(T_D - T_m) \), and the surface heat transfer rate (Refs. 1 to 5).

In most studies of film cooling with slot or discrete hole injection, the local adiabatic wall temperature was computed from the measured heat transfer rate. For this process, the boundary layer analysis was used. However, within the region near the injection, strong mixing invalidates the use of the heat transfer coefficient based on a well-developed boundary layer.

A systematic study of coolant injection through a hole into a crossflow and the concept of an equivalent slot width to correlate all data of slot and hole injection was described in reference 3. The experimental investigation of the effects of constant mainstream acceleration on effectiveness and heat transfer has shown that the mainstream acceleration increases the effectiveness downstream of a single hole (ref. 4). The interaction due to a jet entering normally into a free-stream has been studied with particular attention to the visualization of the large scale flow interaction (ref. 5), and the film cooling downstream from a single normal jet yields a lower centerline effectiveness compared to an inclined jet because of greater mixing with freestream. In reference 6 infrared thermography was used to measure the local adiabatic wall temperatures in the film cooled area of a plate. The test conditions involved low speed crossflow velocity \( (U_c \leq 100 \text{ m/sec}) \), ambient freestream temperatures, and coolant temperatures approximately 20 degrees below ambient. Only single hole injection was investigated and the coolant hole was inclined 30 degrees in the direction of the crossflow (\( \alpha_D = 30^{\circ} \)). Knowing the distribution of wall temperature and the temperatures of the coolant air and the freestream, the effectiveness distribution, or footprint, was readily ascertained.

Recently a three-dimensional finite difference procedure (ref. 7) has been applied to the problem of predicting the flow and thermal fields arising from the injection of fluid in discrete jets through a wall into a crossflow. An example was presented to simulate a gas turbine blade cooled with a single row of holes aligned at 30 degrees to the blade surface. Such an analysis is very complicated, time consuming on the computer, requires complex boundary conditions, and does not lend itself to easy parametric variations that reflect changes in the mixing process between the coolant and freestream. One of the principal objectives of the current research is to evaluate the influence of mixing on the effectiveness. There appears to be a need for an analytical model that is amenable to parametric, or modeling, changes.

Reported herein is a two-dimensional integral method which will predict the local centerline adiabatic wall temperature and the coolant coverage area within a short dimensionless distance downstream of a 30 degree inclined coolant injection hole. Assumptions were made about the coolant layer cross-section shape and the entrainment mech-

ANALYSIS

The flow field is dominated by the mixing process and the pressure gradient caused by the rapid changing in direction in the initial stage. The boundary layer flow along the wall surface is neglected and the viscous effect \( (T_w) \) to the momentum conservation equation is not included.

A. Assumptions

1. The flow is steady and the wall surface is adiabatic.
2. The velocity is uniform within the cross section normal to the axis of the mixing layer.
3. The coolant flow cross sectional area changes from a circle at the coolant exit to an ellipse at location bb (Fig. 1) and the ratio of minor axis to major axes varies linearly from 1 to 0.25 as a function of \( Z/D_o \). Similar elliptical cross sections with \( d/D_c \) exist after location bb.
4. With an adiabatic wall and low speed flow \( (M < 0.3) \), the local adiabatic wall temperature equals the local total temperature of the mixing layer, \( T_{aw} = T_w \).

B. Governing Equations

The theoretical analysis of a jet injected into a crossflow (ref. 9) is utilized. The energy conservation equation is added to solve the local total temperature.

(1) Streamwise Momentum Equation

\[
\frac{dp}{dz} + \frac{d}{dz} \left( \int_A \rho u^2 dA \right) = \rho U_m \cos \theta
\]

With the aid of Euler's equation of the external flow,

\[
\frac{dp}{dz} = \rho U_m^2 \sin \theta \cos \theta \frac{d\theta}{dz}
\]
The streamwise momentum equation becomes

\[ \frac{A}{2} \rho U_m^2 \sin 2\theta \frac{dU_m}{dZ} + A U_m^2 \frac{dA}{dZ} + 2\rho A \frac{dU_m}{dZ} + \rho U_m^2 = -\rho U_m \cos \theta \]  

(1)

(2) Momentum Equation Normal to the Centerline

The surface forces and centrifugal body forces are equal to the momentum flux due to entrainment. The emerging jet is treated as if it were a solid body in computing its contribution to the drag. A drag coefficient \( C_D \) is utilized for this purpose and the normal force is expressed as

\[ C_D \frac{\rho U_m^2}{2} \sin^2 \theta \frac{dA}{dZ} + A \rho U_m^2 \frac{dA}{dZ} = -\rho U_m \sin \theta \]  

(2)

(3) Energy Conservation Equation

With the adiabatic wall assumption, conservation of the total enthalpy in the coolant mixing layer results in the following energy balance equation:

\[ \frac{d}{dZ} \left( \int_A \rho U T \, dA \right) = m \rho T_0 \]  

For constant \( C_p \), the above equation becomes

\[ \rho U \frac{dA}{dZ} + \rho A \frac{dU}{dZ} + T A \frac{dU}{dZ} + T A U \frac{dA}{dZ} = m \]  

(4)

(5) Equation of State

Assuming the equation of state of an ideal gas is valid in the coolant mixing layer, with the aid of Euler's equation, the equation of state can be written as

\[ \frac{1}{2} \rho U_m^2 \sin 2\theta \frac{dU_m}{dZ} - R \left( \frac{U_m^2}{C_p} \right) \frac{dP}{dZ} + R \frac{dT}{dZ} = 0 \]  

(5)

where \( R \) is the ideal gas constant.

(6) Entrainment Mass Flow Rate, \( m \)

To solve \( U, \rho, T, A, \text{ and } \theta \) from equations (1) to (5), the entrainment mass flow rate must be estimated. The following correlation similar to the equation used in reference 10 is employed:

\[ m = \rho E_1 U_m A \sin \theta \]

\[ + \left( \rho E_2 U_m - U_m \cos \theta \right) \frac{dA}{dZ} \left( 1 + E_3 U_m \sin \theta \right) \]  

(6)

where \( E_1, E_2, \text{ and } E_3 \) are empirical constants. The effect of the approaching freestream particles to jet entrainment is modeled in the

first term of the right side of equation (6) and the entrainment due to the freestream moving along the edge of the coolant layer is accounted for by the second term. In surface film cooling, the cooling layer attaches to the wall surface and a factor of 2 was inserted in equation (6) to consider the effective unit surface area for entrainment evaluation in the present inviscid analysis.

C. Cross Sectional Area of the Coolant Mixing Layer

Employing assumption (3), geometric relations for the mixing layer cross sectional area are derived.

From \( \text{aa to bb in Fig. 1} \),

\[ d/D = 1 - 0.433 \left( Z/D_0 \right) \]  

(7)

\[ C = \frac{nD}{2} \left[ 1 - \left( 1 - 0.433 \frac{Z}{D_0} \right)^2 \right]^{1/2} \]  

After location \( \text{bb} \),

\[ d/D = 0.25, C = 2.24D, A = nD^2/16 \]  

(8)

II. Boundary Layer Effect

The effect of boundary layer development along the adiabatic wall surface after the reattachment of the coolant mixing layer is considered. A two-dimensional boundary layer is assumed.

A. Assumptions

(1) The pressure distribution is imposed by the main cross flow and the streamwise pressure gradient is zero due to constant \( U_m \).

(2) The wall beneath the boundary layer is adiabatic.

(3) Both laminar and turbulent boundary layers are considered. Expressions for flat plate boundary layer parameters are valid.

(4) The local total temperature is constant across the boundary layer and the local static temperature equals the local total temperature within the low speed mixing layer.

B. Governing Equations

Principles for the development of the governing equations are similar to section I-B. This technique has also been used in reference 5 for tangential slot injection.

(1) Continuity Equation

\[ \frac{d}{dZ} \left[ \rho U \left( H - \theta \right) \right] + \frac{d}{dZ} \left( \int_0^6 \rho U_b dY \right) = m \]  

(9)

(2) Z-Momentum Equation

\[ \frac{d}{dZ} \left[ \rho U_b \left( H - \theta \right) \right] + \frac{d}{dZ} \left( \int_0^6 \rho U_b \partial \right) = \tau_m + \rho U_m \]  

(10)

(3) Energy Equation

\[ \frac{d}{dZ} \left[ \rho U_b \left( H - \theta \right) \right] + \frac{d}{dZ} \left( \int_0^6 \rho U_b T dY \right) = m \rho T_0 \]  

(11)
(4) Equation of State
\[ \frac{dT}{dz} + T \frac{dp}{dz} = 0 \]  
(12)

(5) Entrainment Mass Flow Rate
For two-dimensional flow and \( \phi = 0 \), equation (4) becomes
\[ m = a_{\text{in}} \, U - U_w \]  
(13)

(b) Boundary Layer Parameters (Ref. 11)
For laminar boundary layer
\[ \delta = \frac{1}{2} \left( \frac{mU}{\nu} \right)^{1/2} \]
\[ t_w = 0.332 \nu \left( \frac{mU}{\nu} \right)^{1/2} \]  
(14)

For turbulent boundary layer
\[ \delta = 0.07 \times \left( \frac{mU}{\nu} \right)^{-0.2} \]
\[ t_w = 0.0225 \nu \left( \frac{mU}{\nu} \right)^{-0.25} \]  
(15)

III. Method of Solutions to the Governing Equations

Equations (1) to (5) were solved for the first derivatives of the flow variables as functions of the variables, i.e.,
\[ \frac{df_i}{dz} = f_i(p, U, T, A, \phi) \]  
(16)

where \( f_i = \rho, U, T, A, \) or \( \phi \).

Including the boundary layer flow effect, equations similar to equation (16) can be derived by substituting the assumption, equations (14) and (15), into equations (9) to (11), and resulted as
\[ \frac{dg_i}{dz} = g_i(p, U, H) \]  
(17)

where \( g_i = \rho, U, \) or \( H \).

These two sets of equations were solved numerically as initial value problems, using the fourth order Runge-Kutta method, to determine the local values of \( \rho, U, T, A, \) or \( H \). Coolant existing conditions were the initial conditions for equation (16). The inviscid flow solution from equation (16) at the location where \( \phi = 0 \) were used as the initial conditions in solving equation (17). The local total temperature, with the boundary layer effect, was obtained from equation (12) after the local density was computed from equation (17). With the assumption that the local total temperature equals the local adiabatic wall temperature in a low speed coolant mixing layer, the local effectiveness, \( \eta = \left( \frac{T_{in} - T_{ad}}{T_{in} - T_{oc}} \right) \times \left( \frac{T_{in} - T}{T_{in} - T_{oc}} \right) \) could be computed from these numerical results.

RESULTS AND DISCUSSION

1. Inviscid Analysis

Different values of the empirical constants, \( C_0, E_1, E_2, \) and \( E_3 \) have been used in equations (16) to find the best agreement in local adiabatic wall temperatures from the computed solutions and the experiment (Ref. 6). The process failed to yield a unique value of \( E_1 \) which will give satisfactory agreement for different injection rates. Film cooling effectiveness, based on the computed adiabatic wall temperature with \( C_0 = 2, E_2 = 0.08, E_3 = 3U, \) and \( E_1 = 0.2 \) and \( 0.3 \) respectively for \( \lambda = 0.37 \) and \( 0.54 \) are compared with experimental data in Figs. 2 and 3. The present inviscid analysis predicts a centerline distribution of the film cooling effectiveness over most of the centerline. However, there is large discrepancy for \( Z/Do < 1 \). The effective coverage area, computed from equations (7) and (8) are also shown with experimental data in Figs. 4 and 5. The experimental data are based on the isothermal footprints for \( \eta = 0.1 \). A smaller effective area was computed than was observed experimentally.

The entrainment mass flow rates for \( \lambda = 0.37 \) and \( 0.54 \) with prescribed empirical constants are compared in Fig. 6. The effectiveness of constant \( E_2 \) and the flow direction are significant for \( Z/Do < 3 \). After \( Z/Do = 3 \), a smaller entrainment rate was computed for \( \lambda = 0.54 \) than \( \lambda = 0.37 \) due to the velocity difference within the coolant layer.

To investigate the present geometry assumptions, the inviscid flow direction, major axis of the elliptical cross section, and the differences between the normal distance from the center of the analytical mixing layer to the wall and half of the minor axis are plotted for \( \lambda = 0.37 \) in Fig. 7. The flow angle, \( \phi \), within the coolant layer decreases rapidly from location \( \phi \) to location \( \phi_b \). After location \( bb \), a small flow angle, \( \phi \), was computed. Very small difference between \( \phi \) and \( \phi_b \) was found. These computational results show that the coolant layer does not separate from the wall surface with \( \phi_b = 30 \) degrees and \( \lambda = 0.37 \). This is consistent with the flow visualization results in reference 12.

11. Boundary Layer Effect

Results of the analysis with the boundary layer effect are also given in Figs. 2 to 5. The initial conditions for the numerical solution were obtained from the inviscid solution corresponding to the location with \( \phi = 0 \). These locations corresponded to \( Z/Do = 0.8 \) for \( \lambda = 0.37 \) and \( Z/Do = 1.1 \) for \( \lambda = 0.54 \). When compared to the inviscid flow analysis, lower adiabatic wall temperatures were predicted. A laminar boundary layer assumption predicts higher effectiveness than the turbulent boundary layer case. This is consistent with less mixing in a laminar coolant layer. The local Reynolds number, \( \rho U \Delta \), within the coolant mixing layer was computed and found to be of the order of \( 10^5 \) after \( Z/Do \approx 2 \). Thus, a turbulent boundary layer assumption predicts the existing experimental results better than the laminar
assumption. For the present studies, expressions for the wholly developed boundary layer velocity profile, shear stress, and boundary layer thickness were used. To model the boundary layer effect downstream of a discrete hole injection, detail profiles of velocity, coolant concentration, and turbulence are required. Moreover, coolant injection will significantly reduce the local skin friction in a region close to the injection. Therefore, the assumptions made in Section II-B may have contributed to the difference between the analysis and experiment in Figs. 2 and 3. Assuming the coolant mixing layer cross section is an ellipse with $H/\Delta = 0.25$ and using the $H$ values obtained from the turbulent boundary layer assumption, the coolant coverage area was also computed and shown in Figs. 4 and 5. It differs slightly from the results of the inviscid analysis.

### III. Comparison with Existing Analysis

Recently, analyses have been performed for single and multiple hole surface film cooling by numerical solution of the three-dimensional flow field (refs. 7 and 8). The analyses are effective in computing the average film cooling effectiveness far downstream of the injection hole but are time consuming in numerical computation. Equivalent techniques based on tangential slot injection has also been proposed to compute the initial conditions for a boundary layer flow analysis due to inclined hole injection (ref. 3). The analysis presented herein is simple in computation and effective in predicting the centerline local adiabatic wall temperature and the effective coolant coverage area near the injection hole. However, a general correlation for the entrainment mass flow rate, which would be valid for different injection rates, was not found in this study. The assumptions about the coolant mixing layer cross section also need further confirmation. Due to the assumption made in local total temperature and adiabatic wall temperature, the present method is also limited to a low speed coolant mixing layer.

### SUMMARY

Assuming the local adiabatic wall temperature equals the local total temperature, an analysis has been developed to compute the centerline film cooling effectiveness and coolant coverage area beneath the coolant mixing layer downstream of a single film coolant injection hole inclined at 30 degrees to the crossflow. Integral conservation equations are formulated and solved numerically to determine the local adiabatic wall temperature and coolant spreading. Inviscid analysis, assuming elliptical cross section in the mixing layer, predicts the film cooling effectiveness within a small distance downstream of the injection hole. Lower adiabatic wall temperature (higher effectiveness) is found from a two dimensional analysis with a boundary layer effect. Smaller spanwise coolant spreading than the direct measurement from the experiment is computed from the present analytical methods.
