An Investigation of Vegetation and Other Earth Resource/Feature Parameters Using Landsat and Other Remote Sensing Data

I. Landsat

II. Remote Sensing of Volcanic Emissions

Semi-Annual Status Report (#2)
August 1, 1980 to January 31, 1981

Dartmouth College
Hanover, NH 03755

Principal Investigators:
Richard W. Birnie, Assistant Professor of Geology
Richard E. Stoiber, Emeritus Professor of Geology

Researchers:
Emily Bryant, Senior Research Assistant
A. G. Dodge, Area Forester, Cooperative Extension Service (UNH)
Kevin Doran, Assistant Grafton County Forester (UNH)
Tom Stone, graduate student
David Sussman, graduate student
Lawrence Malinconico, graduate student
Stanley Williams, graduate student

Undergraduate Student Assistants

Made available under NASA sponsorship in the interest of early and wide dissemination of Earth Resources Survey Program information and without liability for any use made thereof.
This report covers activities of the Landsat Sensing Research Group (Earth Resources) and of the Volcanic Gas Sensing Research Group (Planetary Science) which work in collaboration with the Goddard Institute for Space Studies, New York; Dr. Robert Jastrow, Director. Dr. Stephen Ungar of GISS is the Technical Officer for this project.

NCC 5-22 supports work which was started in 1974 under NSG 5014. The work described below I. B., (Geology and Geobotany) will in the future be supported under another Cooperative Agreement or Grant.

I. Landsat

The Dartmouth Landsat Research Group continued application studies for Landsat data under the general category of analysis of vegetation cover, especially forestry and geobotany, that is, the effects of soil/earth mineral content on vegetation.

A. Forestry

I. Introduction

In the past half year, we have had some changes in personnel, have worked on applications of Landsat data, developed applications techniques, and have maintained and established contacts with remote sensing colleagues. We have noticed an increased awareness of and interest in the use of Landsat data in New England:

II. Changes in Personnel

Kevin Doran has replaced Ken Sutherland as forestry advisor from the UNH Cooperative Extension Service and has quickly taken
hold of these responsibilities. Emily Bryant has entered the Computer and Information Sciences Program as a Master's candidate and has been working on this project half time. Gibb Dodge's role has remained the same. Undergraduate assistants were Mark Heuberger (fall), and Sally Johnson and Paul Fisher (winter).

III. Applications Projects

A. Investigation of the fanning algorithm as applied to Maine forests was completed, written up as an abstract, submitted, and accepted as a poster for the 15th ERIM Symposium in May, 1981. (Enclosure 1)

B. Deer yard habitat. Mark and Kevin field-checked areas in southwestern New Hampshire which the NH Fish and Game Department had indicated were deer yards. Mark used these areas (largely softwood) to develop signatures for potential deer yard habitat. In a field trip to Canaan, signs of deer were found in two out of four or five areas that had printed out as deer yard. Printouts of three towns in southwestern NH were made with these signatures. Reaction from the Fish and Game Department was positive. We are refining these signatures and developing output appropriate to their needs (e.g. overlays of topography).

C. Gypsy moth defoliation mapping. Tapes were finally acquired, but since they are in the wrong format, there is a delay in using them.

D. Recent report by Cooperative Extension Service (sub contract) is at Enclosure 2.

IV. Techniques

We are writing a program on the Dartmouth computer to calculate pixel coordinates given latitude and longitude and vice versa. Mark
determined ground control point coordinates for a significant portion of New Hampshire; Em and Paul have been writing code for the program.

V. **Maintaining Contacts** - spreading the word.

Em went to GISS in September to meet with Arch Park in regards to his project mapping biomass.

Gibb, Em, and Kevin attended the RSGNNE meeting in Burlington in September.

Gibb and Em gave a guest lecture for Dave Lingren's (Geography) remote sensing class.

Kevin and Em met with Kurt Olson (UNH) to see how his work is going and to catch up on news.

At our invitation, Helen Mustafa and Bob Edwards from the New England Area Remote Sensing System (NEARSS) visited Dartmouth. We discussed NEARSS and remote sensing in New Hampshire.

Gibb, Kevin, and Em visited Bob Barker of St. Regis Paper Company in Jacksonville, Florida. We saw their Forest Resource Inventory System which is being put together now. It incorporates Landsat data as one of many levels of information in their forest inventory.

Article "Landsat for Practical Forest Type Mapping: A Test Case" was (finally) published in *Photogrammetric Engineering and Remote Sensing* Magazine, December, 1980. (Reprint, Enclosure 3)

VI. **Increased Awareness.**

Over the past year or so, a number of projects involving Landsat have cropped up in New England. A Landsat Demonstration
Project backed by ERRSAC has been initiated in New Hampshire. Maine has a similar project started within the last year. Vermont's demonstration project has been underway for a couple of years. The NEARSS group, whose concern is largely with access to real-time ocean and coastline remote sensing data, started gathering information and making plans last spring. The New England Innovation Group (funded by NSF) has a contract from NASA Headquarters to investigate the use of Landsat data on the local and regional government level. All in all, things are starting to cook!

B. Geology and Geobotany

The geobotany group have been involved in refining the data collected over the Mesatchee Creek prospect. A Chi squared statistical test was applied to the aircraft multispectral scanner data and it confirmed the extremely high correlation (>99.9%) of the anomalous spectral data to the mineralized zone. This data has been included in a revised paper sent to Economic Geology. (see previous semi-annual report) This paper has been accepted for publication.

II. Remote Sensing of Volcanic Emissions

This research group consists of Professor Richard Stoiber and Graduate Assistants Lawrence Malinconico, Stanley Williams (Ph.D. candidates) and David Sussman. During the period of this report (August 80 - January 81) they were concerned with:

b. Monitoring volcanic activity in Nicaragua, El Salvador and Guatemala (Foreign travel supported by others)
c. Testing a Mini-Cospec.
d. Reporting various activities at Scientific Meetings.

1. Mt. St. Helens

The RAVE Mission is described in Enclosure 4. Professor Stoiber participated with the group, in the remote sensing of SO₂. This report was presented at a symposium on the Mt. St. Helens Eruption in Washington, DC, November 18-19, 1980 (Enclosure 5). At this meeting, a paper was presented (Enclosure 6) to which Stoiber, Malinconico and Williams contributed. A similar paper was presented at the 1980 AGU Fall Meeting (see below and Enclosure 8, V 39).

2. The group visited Central America again in November - December, 1980. This activity continues the field proofing of the Cospec loaned by Barringer Research, the manufacturer, Toronto, Canada. The field expenses, including travel, for this work, are supported by others (esp NSF) but the work contributes generally to the expertise and reputation of the group. Recent activities have been reported in the SEAN (Scientific Event Alert Network of the Smithsonian Institution) Bulletin #12, Dec. 31, 1980 (Extract at Enclosure 7) and at the 1980 AGU (American Geophysical Union) Fall Meeting Dec. 10-15, 1980 in San Francisco (Abstracts of 3 papers V 132, V 133, V 136, Enclosure 8).

Encl. 1-8, a/s
I. Introduction

Most Landsat classification algorithms used today separate land cover into discrete categories on the basis of presence or absence of a land cover type: "wheat vs. non-wheat". Most landscapes, however, include a mixture of types: trees plus grass in an orchard, or corn plus soy along a field boundary. These would be better classified on the basis of the proportion of the area covered by each type. The "fanning" algorithm was developed at the Goddard Institute for Space Studies by Stephen Ungar, to accommodate mixture landscapes. It quantifies the varying proportions of two "pure" land cover types within a pixel.

II. Description of Algorithm

Assume each pixel to be composed of a mixture of cover type A and cover type B. "Pure" pixels of cover type A have a mean spectral signature specified as $A_1, A_2, A_3, A_4$ where $A_i$ is the energy received at the satellite in the $i$th spectral band. The energies in each of the four Landsat MSS bands may be thought of as the components of a 4-dimensional observation vector $\mathbf{A}$. In a similar manner $\hat{B} = (B_1, B_2, B_3, B_4)$ represents the spectral signature of a "pure" pixel of cover type $B$. In principle, the signature of a pixel composed of a mixture of cover types A and $B$ may be expressed as

$$\hat{S} = n\hat{A} + (1 - n)\hat{B}$$
where $\eta$ represents the fractional area occupied by cover type $A$. As $\eta$ varies from 0 to 1 a "fan" of vectors is formed, ranging in direction from $\bar{B}$ to $\bar{A}$ and terminating on the line joining $\bar{B}$ and $\bar{A}$.

In a real situation, the observed signature of a mixture pixel will generally not terminate on this line. Our technique determines which value of $\eta$ minimizes the difference between observed signature and a theoretical signature terminating on the line. Geometrically, this is equivalent to finding the end point of the theoretical mixture vector by dropping a perpendicular from the observed signature to the line joining the pure types.

The problem may be analytically stated as follows:

If, $\delta S = |\tilde{S}_{obs} - [(\eta \bar{A} + (1 - \eta) \bar{B})]$; find $\eta$ such that $\frac{\partial}{\partial \eta} (\delta S) = 0$. The formal solution is simply the least squares fit determination of $\eta$ among the four values obtained by considering each Landsat band independently.

The fanning algorithm is available in both an unsupervised and supervised mode. In the unsupervised mode, the GISS chaining algorithm is used to allow pixels to chain together into clusters and fans. The algorithm selects the signatures for the pixel pair with the largest separation in each fan as the endpoints or "pure" types. A value of $\eta$ is then determined for each remaining pixel in the fan in terms of these pure types. In the supervised mode, the user specifies the pure type signatures which are applied to a category of pixels defined from some previous supervised or unsupervised classification.
In both modes, the algorithm tests: (a) the value of $\eta$ derived for each pixel for physical reasonableness (i.e., $0 < \eta < 1$, if the fractional area hypothesis for a two component mixture is correct); and (b) the goodness of fit of the observed signature to the fan (i.e., $\delta S = 0$ if the observed vector is close to a theoretical vector lying in the fan).

This study uses only the supervised mode.

III. Application of the Fanning Algorithm in Forestry

One goal of the Earth Resources Group at GISS is to make useful forest type maps with Landsat data. Forest types used in current practical forest inventories in the northeastern U.S. are defined by the proportion of hardwood (deciduous) and softwood (evergreen) trees in an area. Definitions and their interpretation vary from user to user. If the fanning algorithm could provide objective and consistent quantification of forest type proportions, Landsat maps could meet or even surpass users' inventory specifications.

IV. Results to Date

As a test of the fanning technique, a classification was compared with a detailed inventory of ½ million acres of forest land in northern Maine, managed by the Seven Islands Land Company, Bangor, Maine. Landsat data was recorded in August, 1976. The inventory, done the same year, breaks out four general forest types:
A scale for the fan was set up where 0.0 represented pure hardwood and 1.0 pure softwood. One would expect, therefore, to partition the forest types at values of 0.25, 0.50, and 0.75 on the scale. To match inventory acreages on the 29 subareas (townships) of the applications area, however, the scale had to be partitioned at mean values of 0.294 (± 0.046), 0.536 (± 0.044), and 0.642 (± 0.043). Although these values were significantly different from expected, they were consistent across the applications area. This suggested that actual partition values could be determined quite confidently from a sample area. The partitioning determined from two sample townships (10% of the area) was used to make acreage estimates for the four forest types in the applications area. Differences between classification and inventory were within 5% over the area as a whole, and within an average of 22% by township. These differences are similar to those observed in a classification of the same area using a "discrete categories" algorithm.

To test temporal consistency, the fanning algorithm was also applied to Landsat data from July, 1976. Over an application area which was limited by clouds, August partition values were 0.271, 0.522, and 0.638; July values were 0.212, 0.500, and 0.647. Slope of the regression line between dates was close to 1, and correlation was high (0.997).
It can be concluded from the project that the fanning algorithm provides consistent quantification of mixtures of two forest types. Partition values for specific ratios of pure types, however, have to be derived empirically at this point.

V. Advantages of Approach

Several approaches which treat pixels as two component mixtures have appeared in the literature. Two strong points of the GISS approach are:

1) The technique is based on a simplistic physical model rather than a statistical approach, and readily allows for improvement by model refinement (e.g., a more recent version of the algorithm takes into account shadowing and slope effects by permitting the fractional areas of the two components to sum to less than one).

2) In unsupervised mode "pure" type signatures are extracted for the end points in a group of pixels and the mixture ratio is determined for each remaining pixel in terms of these pure types. The algorithm automatically rejects pixels which are inconsistent with the two component mixture hypothesis.

The practical application outlined in this paper provides perhaps the first quantitative evaluation of a mixture classification algorithm for large area inventories.
PROGRESS REPORT  
APPLYING LANDSAT MEASUREMENTS  
TO FOREST RESOURCE INVENTORIES  
May 31, 1980 through December 31, 1980

Kevin Doran and Gibb Dodge, Cooperative Extension Service, coordinated their activities with Emily Bryant, Dartmouth College and other representatives of GISS.

SITE SELECTION

1. Finished developing field maps of deer yard areas in the towns of Washington, Stoddard and Henniker for the N.H. Fish and Game Department. Will deliver to the Department and test usefulness.

2. Select gypsy moth defoliation training sites.

3. Select new spruce-fir defoliation training sites.

GUIDANCE AND EVALUATION

a) GISS on making changes in computer programs to produce better products continued.

b) Dartmouth work-study students - mapping techniques, observing ground truth sites, development of rotation and scale change program.

c) Private landowners with large ownership - using computer maps as field tools

d) Revise and update 1981 work plans

e) Evaluation - analyze computer outputs resulting from GISS program changes

COLLABORATION

1. Serving on Cooperative Extension Service National Task Force for remote sensing - advice to Extension Committee on policy related to Extension activity in remote sensing technology transfer.

2. Update information to the University of Vermont, University of New Hampshire, Maine Forestry Group, GISS, ERRSAC, GSFS, Remote Sensing Group of Northern New England, New Hampshire Fish and Game Department and Office of State Planning and NEARS personnel.

3. Remote sensing meetings with University of New Hampshire and Office of State Planning, and Dartmouth.

4. Met with N.H. Office of State Planning personnel on New Hampshire Landsat demonstration project with ERRSAC.
TECHNOLOGY TRANSFER AND REPORTING

1. Landsat presentations to classes of Dartmouth

2. Generate remote sensing technology to New Hampshire Fish and Game Department and Division of Forests and Lands.

Landsat for Practical Forest Type Mapping: A Test Case

Computer classified Landsat maps agreed to within 5 percent of a conventional inventory of forest lands in northern Maine.

INTRODUCTION

Many people have used Landsat data in mapping natural resources and cultural features (Bauer et al., 1978; Dejece et al., 1977; Gaydos and Newland, 1978; George et al., 1977; Krebs and Hoffer, 1976; Mukai and Takeuchi, 1979; Odenyo and Pettry, 1977). In particular, researchers across North America have reported use of Landsat data in mapping forest resources (Beaubien, 1979; Dodge and Bryant, 1976; Harding and Scott, 1978; Johnson et al., 1979; Kalensky et al., 1979; Kirby et al., 1975; Kourtz, 1977; Mead and Meyer, 1977; Sayn-Wittgenstein, 1977; Titus et al., 1975; Williams and Haver, 1976).

The goal of the Dartmouth forestry section of the Goddard Institute for Space Studies is to use computer classification of Landsat data to make forest type maps which are useful to the field forester. Thus, the person who cruises the forest rather than the upper level manager is the “user” for whom the Landsat maps are being developed.

ABSTRACT: In a cooperative project, computer classified Landsat maps were compared with a recent inventory of forest lands in northern Maine. Over the 196,000 hectare (485,000 acre) area mapped, estimates of area of softwood, mixed wood, and hardwood forest types by the two methods agreed to within 5 percent. Cost of the Landsat maps is estimated at 6.5 cents per hectare (2.6 cents per acre). Although the information derived from Landsat is not yet refined enough to be incorporated in current forest inventories, the techniques used are worth developing.

SEVEN ISLANDS PROJECT

The Seven Islands project developed from a contact with a potential Landsat data user employed by the Seven Islands Land Company, Bangor, Maine. Seven Islands manages 690 thousand hectares (1.7 million acres) of forest land in northern Maine and New Hampshire. They require information about forest types on their lands for management decisions and for taxation purposes. (The state of Maine taxes forest land by applying different values to softwood, mixed wood, and hardwood forest areas.) A detailed inventory of the Seven Islands lands was underway at the time the contact was made. This presented a rare opportunity to test Landsat’s ability to meet practical user information needs: the user requirements were well defined (in the inventory specifications) and there was a product, the standard inventory, against which to measure Landsat mapping performance.

With the cooperation of the Seven Islands Land...
Company, a project was started. The goal was to match their inventory specifications as closely as possible using computer classification of Landsat data, and to create, quickly and inexpensively, a product suitable to submit to the Bureau of Taxation. There is a difference between this and some other Landsat applications projects. Success is measured by agreement with a given inventory, not by agreement with "ground truth" gathered by the Landsat investigators. A positive aspect of this approach is the elimination of biases which Landsat investigators might introduce in gathering their own ground truth.

More specific goals of the project were:

- To map the Ashland District portion of the Seven Islands lands (Figure 1);
- To match computer-classified Landsat categories with Seven Islands inventory categories: softwood, mixed wood, and hardwood forest types, non-forest areas, water, and roads;
- To calculate area for each category in each Seven Islands management unit (units are usually townships or parts of townships); and
- To produce geometrically corrected computer printout maps of the area at 1:24,000 scale.

The following constraints were put on the project in order to approximate an operational situation:

- Minimize the amount of ground truth used in creating and checking the Landsat classification (methods dependent on large amounts of ground truth are suitable only for research situations), and
- Keep track of expenses—human and computer time, cost of data and supplies—to give an estimate of cost per unit area.

THE ASHLAND DISTRICT

The Ashland District, managed by Seven Islands Land Company, consists of land in 29 townships in northern Maine located between 46 and 47 degrees north latitude. In most of the area, the political subdivisions are "unincorporated townships" where there is very little permanent human settlement.

The individual parcels or townships in the Ashland District are not always contiguous and range in size from 400 to 10,500 hectares (1,000 to 26,000 acres). The District comprises a total of 196,356

Fig. 1. Ashland District portion of Seven Islands Land Company lands, an area of about 196,000 hectares (485,000 acres). Individual parcels are not always contiguous and range in size from 400 to 10,500 hectares (1,000 to 26,000 acres).

Fig. 2. Oblique (above) and vertical (below) views of a portion of the Ashland District. The vertical view is an example of the black-and-white infrared photos used in the Seven Islands inventory (original scale 1:15,840; photos taken in May, 1976).
The most common forest types in this area are:
- spruce-fir (Picea sp.—Abies balsamea)
- maple-beech-birch (Acer saccharum—Fagus grandifolia—Betula alleghaniensis)
- northern white cedar—black spruce (Thuja occidentalis—Picea mariana)

Figure 2 shows oblique and vertical views of part of the Ashland District.

THE SEVEN ISLANDS INVENTORY

The Seven Islands inventory is based on aerial photo-interpretation, "3-P" (probability proportional to prediction) field sampling, and the GIS computer program (a standard forest measurement program). Figure 2 includes an example of the photos used in the inventory. The inventory consists of type maps, acreage tallies, and volume estimates. This project concentrated on matching the maps and acreage tallies, leaving volume estimation to other techniques.

The Seven Islands maps distinguish vegetation by type, size, and density to a 10 acre minimum. Acreage is determined for each forest stand, and totals are computed by type for each township. For tax purposes, the many forest types distinguished in the inventory are grouped into three more general types according to the proportion of softwood (conifer) to hardwood (deciduous) trees in an area:
- softwood—at least 75 percent of the trees are softwood.
- hardwood—at least 75 percent of the trees are hardwood.
- mixed wood—the proportion of softwood to hardwood trees lies between those of the softwood and hardwood categories as defined above.

The above are the general forest categories that were to be matched in the Landsat classification.

PROCEDURE

The project employed computer programs to make maps and acreage tallies from Landsat multispectral scanner (MSS) digital data. A supervised classification approach was used. It was developed at the Goddard Institute for Space Studies (GISS) by Stephen G. Unzar and is described in Merry et al. (1977). With the GISs classification algorithm, the program uses a volume in four-dimensional color space around an average signature for each land cover category. The signature is usually the average reflectance of a land cover type as taken from a representative sample of the MSS data (a "training site"). The user can create a classification category for which there is no training site, if there is another source of signatures.

DETAILED OF THE SEVEN ISLANDS PROJECT

Landsat data used in the Seven Islands project was recorded on 11 August 1976. Scene identification numbers are 5480-14040 and 5480-14043 (Figure 3).

Ground truth consisted of:
- Representative copies of the photos used in the Seven Islands inventory (Figure 2);
- Seven Islands inventory maps and acreage tallies for two of the 29 townships in the District;
- Personal knowledge from an overflight of the area;
- Prints of photo-mosaics used for location of forest harvests (scale 1:31,680); and
- Topographic maps (scale 1:62,500);

There was no ground checking except indirectly through the inventory information.

We chose signature training sites in the MSS data (usually 10 to 30 pixels in size) for softwood, hardwood, water, bog, and open categories using the aerial photographs. Mixed wood signatures were made by interpolating between hardwood and softwood signatures.

The tolerance parameters for the forest categories were adjusted so that the acreage tallies would agree with the Seven Islands inventory on two sample townships (Table 1). Discrepancy in acreage figures on the two townships taken together was under 3.5 percent; it was under 10 percent when they were considered separately. The two townships comprise 19,000 hectares (47,000 acres), about 10 percent of the Ashland District (Figure 3).

* Both Seven Islands and Landsat tallies were normalized so that total area in each township matched the deeded acreage as listed in the Seven Islands records.

Boundaries of the management units (townships) were superimposed on the Landsat data using a masking program. They were taken from topographic maps, using water bodies as control points.

Figure 4. Seven Islands Land Company inventory tallies for the Ashland District and Landsat computer classification results for the same area.

Results

Results relative to the Goals

Map the District. A printout map and acreage tally by category was made for each management unit in the Ashland District.

Match Seven Islands categories. Area comparison is one measure of how well the Landsat categories match Seven Islands categories. Area tallies for the entire district are shown in Table 2 and Figure 4. Differences between Landsat and Seven Islands forest type acreage estimates are under 5 percent. As is to be expected, they are larger for the individual township tallies. Figure 5 shows Seven Islands versus Landsat acreage estimates for the individual townships for softwood, mixed wood, hardwood, total forest, water, and open categories. Both the Landsat and the Seven Islands inventory acreage tallies were normalized so that the total acreage in each township matched the deeded acreage as listed in the Seven Islands records.

* The Seven Islands inventory included no "unclassified" category.

** Both Seven Islands and Landsat tallies were normalized so that total area in each township matched the deeded acreage as listed in the Seven Islands records.
Fig. 5. Seven Islands inventory tallies for each management unit (township) are plotted against Landsat computer classification results for six land cover classes. Discrepancies in one township could be attributed to differences in classification of partially cut areas (data point is circled).
its deeded acreage as listed in the Seven Islands records.

Agreement in locations of features on maps was desired as well as area agreement. An informal comparison of Landsat maps and Seven Islands inventory maps shows that the positions and shapes of the forest stands generally coincide (Figure 6). As a more formal test of locational agreement, 130 sample pixels in one ground truth township were selected at random, and their Landsat and Seven islands categories were compared. Results are in Table 3. The overall agreement (diagonal entries in the table divided by the total number of samples; 83/130) is 63 percent. While this seems rather low, other Landsat applications studies involving forest types have similarly low overall agreement, depending on exactly what the categories are, how they are aggregated, and how the samples are chosen (Table 4). Overall agreement ranges from 43 percent to 98 percent.

This single pixel method of measuring classification accuracy has inherent problems. Minimum feature size classified on the ground truth maps is often greater than one pixel (0.4 hectares or 1.1 acres); in this case it was 4 hectares (10 acres). Exact location of one-pixel samples on ground truth maps is uncertain. Each of these problems can lower the measured accuracy of a classification, regardless of its actual accuracy.

In the non-forest categories, it was found that roads were not located with enough accuracy to be useful; also, bogs were often classified as forest, and small streams were not identified.

Tallies for each township. Acreage by township and category is in Figure 5 as mentioned above. Locating township boundaries was very time consuming but essential for comparison with the standard inventory results.

Geocorrected data. The Landsat geometric correction used was a systematic correction applied to the entire Landsat scene, using a nearest neighbor resampling scheme. The accuracy was acceptable over the one-township size units (8000 hectares or 20,000 acres) used in the Seven Islands project.

REMARKS ON THE CONSTRAINTS

Minimize ground truth. Originally, the Seven Islands inventory of the two sample townships

![Image](https://example.com/image.png)

Fig. 6. Seven Islands inventory map (above) and Landsat computer classification (below) from one of the two sample townships. Informal comparison shows that positions and shapes of forest stands generally coincide. Landsat data has been systematically geometrically corrected (original scale 1:24,000).
was not included in ground truth. Preliminary results, however, showed a large discrepancy between Landsat and inventory maps. The only way to match given categories was to have a sample of them, not just the inventory specifications. Since the size of the ground truth sample townships was large, the original goal was expanded from mapping three townships to mapping the entire district.

Costs. The cost estimates for this project are listed in Table 5. The overall cost of 6.5 cents per hectare (2.6 cents per acre) includes human time at ten dollars per hour, computer time at 600 dollars per hour (on an IBM 360/95), and ground truth. The cost of ground truth for the two sample townships is 37 percent of the total cost—2.4 cents per hectare (0.99 cents per acre). The cost also reflects inefficiencies which would be eliminated in subsequent projects. The estimate excludes cost of software development, depreciation on the computer, photo-mosaics, topographic maps, and geocorrection of data. Classification of a larger area would reduce the per area cost; estimated cost for 800,000 hectares (2 million acres) is 2.4 cents per hectare (0.96 cents per acre). Table 6 compares this cost estimate with those from other Landsat applications projects. They vary from 0.078 to 8.6 cents per hectare (0.032 to 3.5 cents per acre). Much of this variation is due to differences in the items included in the estimates (sometimes ground truth is excluded) and the cost assigned to the items (cost of human time varies from 5 to 21 dollars per hour).

The information derived by computer-classification of Landsat data could also be derived from standard photo-interpretation techniques. The company that did the Seven Islands inventory gave a ball-park estimate of the cost as 11.0 to 16.0 cents per hectare (4.5 to 6.5 cents per acre). (Rate for the Seven Islands inventory itself would be higher because it is more detailed).

Discussion

Although acreage results on the forest categories were within 5 percent, those for the remaining categories (water, bog, open land) had much larger discrepancies (Table 2; Figure 5). Possible explanations of these discrepancies follow. First, there is a smaller sample: together the open, bog, and water categories comprise only 5 percent of the

* Information not provided.
area classified; the rest is forested. Next, the resolution of Landsat (80 metres) is coarse relative to streams and narrow roads. These features are absorbed into the surrounding forest types. This may account for the Landsat underestimation of water and open categories.

Confusion in Landsat categories may account for the underestimation of the bog category. Bogs were often classified as mixed wood or hardwood.

Forest acreage tallies for some individual townships had noticeably large discrepancies. In one case (circled in Figure 5) this could be attributed to differences in classification of partially cut areas which included many small softwood trees and a few large hardwood trees. The photo-interpretation in the Seven Islands inventory, which is based on numbers of trees, indicated softwood; the computer classification, based on average reflection, indicated mixed wood.

A factor influencing forest classification is sun illumination. Classifications of forest areas within terrain shadows have a bias toward softwood. Merging of digital topographic data and Landsat data could improve this situation (Krebs and Hoffer, 1976; Strahler et al., 1979). Over a large enough area, these differences balance each other out.

There are some problems which researchers cannot solve. One is New England weather, which is relatively cloudy. It is possible that in some years there would be no Landsat coverage at the desired times of year. Another problem is the acquisition of data. At this point there is a long turnaround time in ordering Landsat computer compatible tapes (CCT’s). Also some private organizations do not want to depend on government sources for their data.

## CONCLUSION

Bearing in mind the objective to give quick, inexpensive, and accurate acreage estimates of forest types to the Bureau of Taxation, the following conclusions are drawn. Results were very good on the district as a whole, but were not good for the individual townships. Each township has unique records of accounting and ownership and must have proven and precise forest type information. In some cases this is needed for portions of a township that are as small as 400 hectares (1000 acres). The 400 hectare tract requires the same level of precision that was reached in this project with the tallies for the 200,000 hectare tract.

On the other hand, the energy situation is becoming more burdensome, and satellite information will become more important as a supplement to aerial photographs and other information sources. Further research in satellite data processing techniques could bring the information to a more usable level and is worth pursuing.

## RECOMMENDATIONS

More experience using satellite data in practical situations is recommended. Computer classification may currently be as reliable as photo-

\(^3\) Estimated cost for 10,000 hectares (48,000 acres) at $25 per hectare ($10 per acre).

\(^4\) Includes 200 hours labor and 144 minutes computer time (valued at $10 per minute).

\(^5\) Includes 106 hours labor and 90 minutes computer time.
LANDSAT FOR PRACTICAL FOREST TYPE MAPPING

1583

interpretation, but there are differences, and they need to be identified. Perhaps some of the information missing in the current Landsat maps can be extracted from higher resolution data such as the quarter acre resolution projected for Landsat D (Williams and Stauffer, 1979). Already, examination of Landsat 3 MSS imagery suggests that woods roads will be much more distinct with 30 metre resolution.

SUMMARY

Landsat classification maps were made for a forested area in northern Maine, managed by the Seven Islands Land Company. Over the 200,000 hectare (half million acre) district, results agreed with a standard inventory to within 5 percent on area of general forest types. Cost was estimated at 6.5 cents per hectare (2.6 cents per acre). Accuracy measurements and cost estimates were comparable with other Landsat forestry applications projects.

The techniques described here are promising, but are not yet practical for Seven Islands Land Company’s needs. Further research and perhaps better spatial resolution are needed to ensure reliable Landsat results on smaller geographic areas.

ACKNOWLEDGMENTS

This project was supported by NASA Science Grant 5014. We wish to thank Seven Islands Land Company for their cooperation and for the use of inventory data.

RESULTS OF THE SEPTEMBER 22, 1980 RAVE STUDY
OF THE MOUNT ST. HELENS PLUME

Jarvis Moyers
University of Arizona

This paper presents a description of the joint University-NASA research project RAVE (Research on Atmospheric Volcanic Emissions) and preliminary results from a recent Mount St. Helens expedition. The RAVE scientific team consists of scientists from Drexel University, Dartmouth, Michigan Technological Institute, University of Arizona, University of Maryland, and NASA. A Lockheed Orion P-3 four engine turbo-prop aircraft has been outfitted with active and passive instrumentation for monitoring and sampling gases and aerosols in volcanic plumes. The first field study in this project was performed on September 22, 1980 at the Mount St. Helens volcano. Measurements made in this study include remote sensing of $\text{SO}_2$ and aerosol burdens and fluxes; in plume analysis of $\text{SO}_2$, $\text{H}_2\text{S}$, NO, $\text{NO}_2$, $\text{O}_3$ and particle size distribution; and the filter collection of aerosols and reactive gases for subsequent laboratory analysis. There was a very successful integration and operation of all onboard equipment and experiments. Available results obtained in this are presented and discussed.

The resumption of volcanic activity at Mount St. Helens in
March 1980 prompted measurements and study of CO₂ and SO₂ emission rates. The objective of these studies is to provide information
about the degassing of the subsurface magma body. Although the
principal propellant of the explosive eruptions at Mount St. Helens
is probably H₂O vapor, emission rates for CO₂ and SO₂ may also be
useful indicators of volcanic activity. Significant changes in
emission rates for these gases may occur as a result of various
factors such as migration of gases from deeper magma, intrusion of
magma toward the surface, changes in the concentrations of CO₂
and/or SO₂ in the silicate liquid, changes in the degassing rate
of the silicate liquid, and changes in the permeability of the vent.
Aside from providing information relevant to eruption mechanisms, the
measurements of sustained gas emissions together with the pre-eruption
volatile concentrations provide a basis for inferring the presence
of a magma body and for estimating the volume of degassed silicate
liquid remaining at depth. The total amounts of CO₂ and SO₂ released
to the atmosphere by magma degassing during non-eruptive periods
at Mount St. Helens can be estimated from the more than 70 measure-
ments of emission rates. One must increase these numbers by the
amounts released during explosive eruptions.

Volcanic Activity
Tarumai Volcano (cont.)

Figure 3: Monthly numbers of days in which eruptions occurred (top); harmonic tremor events (center); and recorded earthquakes (bottom) at Tarumai, January 1978 - December 1980.

Mayon Volcano, SE Luzon Island, Philippines (13.26°N, 123.62°E). All times are local (= GMT + 8 hours).

A moderate quantity of dirty white steam rose weakly to 200 m above the crater rim on 4 December at 1247, accompanied by short-duration harmonic tremor on the Mayon Resthouse Observatory seismograph. Faint crater glow was first noted at 2315 the same day. Additional steam emission was observed 12 and 14 December.

Harmonic tremor was first recorded at Mayon on 16 August (see SEAN Bulletin v.5, no. 8). Episodes of tremor and discrete earthquakes continued through December. Similar seismic activity preceded the 1978 eruption (see SEAN Bulletins v.3, nos. 2, 5, and 8) and accompanied crater glow in July 1979 (see SEAN Bulletin v.4, no. 8).

Volcanic Activity in Nicaragua, El Salvador, and Guatemala, late 1980

Geologists from Dartmouth College, the Instituto Geográfico Nacional of Guatemala, and the Instituto de Investigaciones Sismicas of Nicaragua observed 8 Nicaraguan, 2 Salvadoran, and 2 Guatemalan volcanoes between mid-November and early December. Dartmouth geologists provided the following report.

Nicaragua

Cerro Negro (12.52°N, 86.73°W) - Summit crater fumaroles remained at temperatures as high as 300°C. A small vapor plume was intermittently visible. Seismic activity had dropped from the high level of June.

Cosiguina (12.97°N, 87.58°W) - No fumarolic activity was visible from the rim.
Volcanic Activity
Nicaragua, El Salvador, Guatemala, (cont.)

Las Pilas (El Hoyo) (12.48°N, 86.68°W) - A small continuous vapor plume was still being emitted from the top of the km-long crack in the summit.

Masaya (11.95°N, 86.15°W) - Emission of a very large gas plume has continued without interruption since fall, 1979. Remote sensing of SO2 revealed continued high level flux, with 1,500 - 2,000 tons/day average for the entire year. The hole through the surface of the lava lake was larger than in previous years and a great deal of sublimation was occurring around its edge. No lava or red glow was visible during daylight. Acid gas and rain continued to cause considerable damage downwind.

Mombacho (11.83°N, 85.98°W) - A small, intermittent plume was visible, rising from the SE section of the summit.

Momotombo (12.42°N, 86.55°W) - The summit crater fumaroles continued to be very hot with temperatures measured up to 735°C and reported to >900°C. A small vapor plume continued and remote sensing revealed very low rates of SO2 emission. Portions of the crater were seen to glow red and orange when observed at night, with the highest temperatures on the steep S wall of the crater. No seismic activity has occurred recently at Momotombo.

San Cristóbal (12.70°N, 87.02°W) - A moderate-sized vapor plume rose continuously from the summit. Remote sensing of SO2 revealed increased flux since June 1980, but SO2 emission remained far below the levels of the mid-1970's.

Telica (12.60°N, 86.87°W) - A moderate-sized but continuous vapor plume rose from the summit crater. SO2 flux was remotely measured and found to be approximately 150 tons/day.

El Salvador

Observations were made during a flight over the country.

Santa Ana (13.85°N, 89.63°W) - A moderate plume rose from a bank of fumaroles on the SE wall of the inner crater, very similar to its appearance in November 1978.

San Miguel (13.44°N, 88.27°W) - A small, continuous vapor plume rose from the summit crater.

Guatemala

Pacaya (14.38°N, 90.60°W) - A very small cinder cone had grown inside MacKenney Crater in the last 2 months. A large gas plume rose continuously from the summit.

Santiaguito (14.76°N, 91.55°W) - Ash and gas eruptions from Caliente vent (at the E end of Santiaguito Dome) occurred irregularly over the 3-day period of observation, with intervals of 1/2 hour to 4 hours between eruptions. Most eruptions lasted 2-3 minutes and sent ash and gas columns to heights of several hundred m to 1 km above the vent. Five mm of ash accumulated at the foot of the dome over one 12-hour period. Eruptions
Volcanic Activity
Nicaragua, El Salvador, Guatemala (cont.)

occasionally threw 10-cm blocks several hundred m and ejected tephra to
well above the summit of Santa María. Although not directly observed,
the plug dome and blocky lava flow that was seen being extruded from
Caliente vent in February was apparently still very active. Large
avalanches of glassy material could be heard from Caliente vista many
times per hour. Debris from these avalanches was visible in the barranca
below Santiaguito.

The Algeria event injured 20 persons in the El Asnam area, devastated
by earthquakes 10 October that killed thousands and left about 400,000
homeless (see SEAN Bulletin v.5, no. 10). There were no reports of casu-
alties or damage from the 17 December shock. The 19 December earthquake
killed 26 persons. The nearby event 3 days later caused 3 deaths and 139
injuries according to official reports.

Earthquake Swarm
Siquijor Island, Philippines.

A swarm of earthquakes began to be felt at Lazi, on the S coast of
Siquijor Island, on 17 December. By 19 December, recorded events averaged
102/hour and several may have reached magnitude 4-5. Loud detonations re-
portedly accompanied the seismicity. The next day, 95 strong earthquakes
1980 AGU FALL MEETING

December 10-15, 1980, San Francisco
The 1980 Eruption of Mt. St. Helens IV
Emerald Room HI
Tuesday PM
Robert L. Christiansen (USGS), Stephen D. Malone (U of Washington), Presiding

The recent eruptions of Mount St. Helens illustrate the important effects which large volume volcanic eruptions may have on the atmosphere, which in turn could effect climate. Mt. St. Helens and many other explosive volcanoes may produce such large and strong atmospheric effects that they have been called "super-eruptions". The plume transport will likely initiate air temperature changes and may mask any underlying climate signals. Yet the impact of Mt. St. Helens on the climate of the northern hemisphere may be quite significant. We have compiled a large data base on the plume from additional super-eruptions that have occurred in recent years. This data is being synthesized for a major report that will be published in the near future. Always available on request.

This page may be freely copied
The concentration of Fe, Al, and Na has been determined in 37 silicate liquids, covering virtually the whole natural range of liquids, quenched from superliquidus temperatures (1200-1350°C) and with moderate system pressure (1 atm) from P-T. In conjunction with published data, the formation of the compositions of the non-compositional silicate liquids has been fitted by a semi-empirical equation relating the lattice oxygen of the superliquidus Fe, Al, Na, and Mg and the following temperature and the composition of the liquid as follows:

\[ \log f_0 \approx 3.2185 \times 10^4 + 0.99965 \times T \]

where \( f_0 \) refers to total iron calculated as FeO, Oxygen fugacities calculated for the analysis samples of the Nakahara lava tube are systematically low by 0.1 to 0.15 log units, depending on temperature, but the correspondence with values obtained from mixing calculations is good. The highest acid earthquake of the silica-rich liquids is higher than the FeO content in the same liquid (in the same way) than is typical of basaltic lavas, though there were many basaltic lavas to counteract both oxygen fugacities and lower alka sility due to the composition of their silicate counterparts.

V. 127

ACCURATE FIRST PRINCIPLES (ISOThERMIC FOR NaCl)

R.P. Robinson (Dept. of Geology and Geophysics, University of California, Berkeley, CA 94720)

The ionic strength of NaCl, frequently used for pressure calibration, has satisfactory accuracy to pressures of the order of 150 kilobars. We report an attempt to generate accurate theoretical isotherms for NaCl that are reliable to 300 kilobars.

The Na ion is used with the aid of a first principles calculation of the average spectrum and charge density in the NaCl structure. The Augmented Plane Wave method was used to obtain the self-consistent band structure. The charge and correlation interactions are approximated by the Molière-Lindquist potential, and the parameters are adjusted by a modified version of the virial theorem. The predicted Na lattice constant of NaCl is in good agreement with the best available estimates, as are the zero pressure bulk modulus and its pressure derivative. Since the accuracy of the theoretical methods is not complete, we feel that a very accurate NaCl isotherm is being generated with the aid of available thermodynamic data, including the temperature dependence of the expanded parameter. Room temperature results will be compared with X-ray scattering and will be submitted to the 128th Conference of the American Chemical Society.

V. 128

DISTRIBUTION KINETICS OF SELECTED SILICATE MINERALS UNDER ACID CONDITIONS

D. L. Siegel (U.S. Geological Survey, St. Paul, Minnesota)

The dissolution of biotite, muscovite, muscovite, and feldspar in the aqueous system was investigated at near neutral to slightly alkaline pH and constant ionic strength of 1,000 to determine the kinetics of release of silica, calcium, and magnesium. Release of cations and silica followed monomolecular rate processes, whereas the dissolution rate of potassium was first order, initial linear rate and then 7,000 hours of reaction time. Estimated linear rates ranged from 10^-7 to 10^-5 moles per cm^2 second per second for calcium.

V. 129

THE PARTITIONING OF FeO, Fe, Mn, and ACl BETWEEN A SILICIC MELT AND A CL FLUID

R. A. Webster (Dept. of Geology, Arizona State University, Tempe, AZ 85281)

The partitioning of Si, Fe, and Fe between a silicic melt and a Cl fluid is determined for 10 ppm Sc and 100 ppm Sr. The partition coefficient as concentration in molar ratio 0.1.15 for all elements but Li and by 9.46 I .46 for Sr. The uncertainty is chiefly due to incomplete mole fraction coefficients as concentration in molar ratio.
ash eruptions in 1976, coincident with the highest SO2 flux of thousands of metric tons per day. In 1980 the rate has dropped by 20 tons per day. Volcanic ash, we have measured the beginning of a dramatic new trend. SO2 emissions are now almost an order of magnitude greater than it was in the 1970's. Since 1979 Ash emissions have averaged approximately 25, 50 and 75 years ago and lasted from 5 to 15 years. We continue to study this event. These gradual changes in SO2 flux correlate with short-term increases in five or more of the gaseous species we have measured at Mt. St. Helens, Sicily.

In the Introduction of greater than 80 gigatonnes, Sui-

Richard E. Stickler

Lawrence L. Williams

Stanley W. Williams (San Diego State University, San Diego, CA 92182)

N. C. Miller, Jr. (Taiwan Institute of Geophysics, National Taiwan University, Taipei, Taiwan 11142)

The correlation between the SO2 and H2S concentrations in several volcanic plumes in Taiwan and Hawaii. In 1979 an anomalous increase in the SO2 flux of ~500 ppm occurred in several volcanic plumes in Hawaii. The increase in SO2 flux is thought to be due to the eruption of a new volcanic plume from a source other than the active summit. The SO2 flux is currently being monitored to determine the long-term effects of the eruption.

R. A. Engle (Air Pollution Research Section, Environmental Protection Agency, Washington, DC 20460)

We report on the analysis of air samples collected during the Mt. St. Helens eruption. The samples were collected using passive samplers and analyzed for SO2, CO2, CO, H2S, and H2, using gas chromatography and mass spectrometry. The results show that the atmosphere is being contaminated by SO2 and H2S, which are emitted from the volcano. The concentrations of these gases are highest near the summit and decrease with distance from the vent. The SO2 and H2S concentrations are also highest during the daytime hours, when the wind is blowing from the volcano.

Extensive airborne measurements have been obtained of the particles and gases emitted during the explosive eruptions of Mt. St. Helens, Alaska, in 1975 and Mt. St. Helens, Washington, in 1980. Both produced pyroclastic flows representing a range of source materials from anesite to dacite. The 1975 eruption consisted of three periods of pyroclastic flows, each occurring in early summer and April 1975. Our measurements were made during the period of activity, using a variety of instruments. In April 1975, our measurements of the Mt. St. Helens eruption have covered the entire eruption sequence, including pre-eruptive, eruptive, and post-eruptive phases, and include several of the major event.

The size distributions of particles measured during the eruptions are remarkably similar. In both cases the particles consist mainly of pyroclastic-rich particles (with a small water soluble component). Strongly acidic emissions, with a major sulfur component characteristic of the pyroclastic-rich phase of both volcanoes. The volcanic plume from Mt. St. Helens consisted largely SO2, until more than a year after the 1975 eruption. In the 1980 eruption, the SO2 flux from Mt. St. Helens has been significantly lower than that of the volcanic plume. The 1980 eruption was characterized by a very high SO2 flux, which was probably due to the high temperature of the pyroclastic material. The 1975 eruption was characterized by a very low SO2 flux, which was probably due to the low temperature of the pyroclastic material.

The greatest natural contribution of SO2 gas and aerosol to the troposphere in 1980 was observed from the Mamanuca Islands of the Republic of Fiji. In September, 1980, approximately 300,000 metric tons of SO2 were emitted from the volcano, which was the largest emission of any known volcano. The SO2 emissions were monitored by the University of Washington and the University of Alaska. The SO2 emissions were measured by a variety of methods, including gas chromatography and mass spectrometry. The results show that the SO2 emissions are primarily from the pyroclastic material.

Gas chromatographic analyses have been made of the gases emitted from the June and August 1980 eruption clouds from Kilauea, Mauna Kea, and Mauna Loa. The results show that the gases emitted from these eruptions are mainly CO2, H2S, and SO2. The gases emitted from the June 1980 eruption are mainly CO2 and H2S, while the gases emitted from the August 1980 eruption are mainly SO2 and H2S. The results indicate that the gases emitted from these eruptions are mainly CO2, H2S, and SO2. The gases emitted from the June 1980 eruption are mainly CO2 and H2S, while the gases emitted from the August 1980 eruption are mainly SO2 and H2S.
