IUE OBSERVATIONS OF VARIABILITY IN WINDS FROM HOT STARS

C.A. Grady and Theodore P. Snow, Jr.
LASP, University of Colorado at Boulder

ABSTRACT
Observations of variability in stellar winds or envelopes provide an important probe of their dynamics. For this purpose a number of O, B, Be, and Wolf-Rayet stars have been repeatedly observed with the IUE satellite in high-resolution mode. In the course of analysis, instrumental and data handling effects were found to introduce spurious variability in many of our spectra. Software has therefore been developed to partially compensate for these effects, but limitations remain on the type of variability that can be identified from IUE spectra. With these constraints, preliminary results of multiple observations of two OB stars, one Wolf-Rayet star, and a Be star are discussed.

TEXT
Observations of variability in stellar winds or envelopes provide an important probe of their dynamics. IUE, with its ability to simultaneously sample large portions of the ultraviolet spectrum, can potentially enable one to relate temporal variations in one spectral feature to other lines. Ultimately this may yield a spatial as well as spectral probe of the outer atmospheres of hot stars. Before any such analysis can be undertaken, however, it is essential to determine the type and amplitude of variability which can be measured from IUE high-resolution spectra.

Reduction and analysis of IUE high-resolution data for temporal variability is complicated by a number of instrumental and data handling effects which can introduce sufficient spurious variability into the spectra to swamp any real stellar variability. These effects and programming to partially compensate for them developed on the PDP 11/34 of LASP/University of Colorado using the Interactive Data Language are discussed by Grady (1). Limitations do remain on the amplitude of line profile variations that IUE is capable of detecting in high resolution. For example, in order to compensate for differing exposure times and positioning of the target star in the spectrograph slit, all of our data has been normalized to the continuum = 1. As a result, it is impossible to monitor changes in continuum level. Thus, our effort has been concentrated on changes in profile shape and relative intensity in a number of lines known to indicate mass loss. (2)

It is then necessary to determine the changes in relative flux which can be confidently attributed to the star, rather than the instrument and subsequent data handling. One of the stars in our variability search, α Cam (HD 30614, 09.5Iab) showed no evidence of any change in its P Cygni profiles to the limits imposed by noise in the data when observed nearly continuously for three days in September, 1978, for a total of 75 exposures, when reobserved once a month later, and again in January of 1979. For this reason, this
star has been chosen to determine the noise limits in different parts of
the SWP spectrum. Only SWP spectra are considered in this paper, as we are
still awaiting our reprocessed LWR spectra. Table 1 gives the limits on
change in relative flux level as a percentage of the zero to continuum
level. To be confident that the change in flux level is stellar, rather
than instrumental or processing-induced, the further constraint has been
imposed that the change in the flux level must be sustained over a 0.1A
interval. Changes over smaller intervals may be real, but a detailed
examination of gross and background records for each image would be essential
in order to determine whether or not this is the case.

OBSERVATIONS
Even with these conditions, three stars surveyed to date show clear evi-
dence of temporal variations in their P Cygni profiles. Analysis is still
in the preliminary stages for all three. They are κ Cas (B1 Ia, HD 2905);
59 Cygni (Be, HD 200120) and γ² vel (WC8 + 091, HD 68273).

κ Cas was observed as part of a cooperative program with H.J.G.L.M. Lamers,
C. deJaeger, and F. Machetto. It was observed for 29 hours in alternation
with α Cam on Sept. 9-10, 1978. A total of 26 SWP high-resolution exposures
were made during this time with exposure times of 6-10 minutes. All profiles
were constant to within the limits of detection. On Oct. 12, 1978 a single
exposure of κ Cas was obtained. The fully-saturated P Cygni profiles
showed no changes in shape or relative intensity beyond the noise limits.
The two unsaturated profiles, CII λ1335, and AIII λ1854, λ1862 did show
noticeable changes. The CII P Cygni profile appears slightly broader in
the October spectrum than in the Sept. data. It was not possible to measure
the edge velocity for this line as the profile lacks a sharp short wavelength
absorption edge. The changes in the AIII profile are much larger. In the
September observations only the AIII λ1854 line has a well developed Type
I P Cygni profile (see Fig. 1). A saturated emission feature is present at
the wavelength expected for the λ1862 emission. Weak absorption is present
shortward of this feature. In the October observation both AIII components
are clearly present, although the λ1862 line suffers from an instrumentally
saturated emission peak. The emission part of the λ1854 profile appears to
be about the same as in September. Likewise, the edge velocity, as measured
from the λ1854 line, appears to be constant. The striking changes in the
absorption component occurs at the red side of the absorption feature, in
the velocity range -(410-710) ±20km/sec.

59 Cygni was observed in cooperation with V. Doazan, R.N. Thomas, L. Kuhi,
and J.M. Marlborough. Data has been processed at LASP only for observa-
tions made in June and September of 1979. Data handling problems have
prevented analysis of all ions with the exception of CIV λ1548.188, λ1550.762.
(See Fig. 2) In June, 1979 the doublet is blended together in absorption.
The profile appears to be saturated. By September, however, both components
are clearly visible. How this correlates with changes in other orders is
not yet known. A cursory examination of SiIV λ1400 indicates that no such
drastic changes occurred for that ion.
\(\gamma^2\) Vel was observed as part of a collaborative program involving K.A. van der Hucht, A. Willis, F. Machetto, R. Wilson, and D. Stickland with some of the data analysis taking place at C.U. We have processed CIII \(\lambda 1176\), SiIII \(\lambda 1206\), NV \(\lambda 1240\), CII \(\lambda 1335\), SiIV \(\lambda 1400\) (Fig. 3), CIV \(\lambda 1550\) (Fig. 4), and NIV \(\lambda 1718\). All of the ions surveyed show some changes in the shape of the absorption part of the P Cygni profile. More dramatically, all show decreased emission at phase 0.53 of the binary orbit. At this phase the Wolf-Rayet star is in front as seen from Earth. With data covering only one orbital period it is impossible to be certain that this decrease is related, but the data are rather suggestive.

CONCLUSIONS

Despite the limits on the amplitude and type of temporal variability that can be confidently detected using IUE in high-resolution mode, it is possible to observe significant time variations in the P Cygni profiles of hot stars.
