HOLOGRAMS FOR LASER DIODE - SINGLE MODE OPTICAL FIBER COUPLING

Peter L. Fuhr
NASA/Goddard Space Flight Center
Greenbelt, Maryland 20771

ABSTRACT

The low coupling efficiency of semiconductor laser emissions into single mode optical fibers place a severe restriction on their use. Associated with these conventional optical coupling techniques are stringent alignment sensitivities. Using holographic elements, the coupling efficiency may be increased and the alignment sensitivity greatly reduced. Both conventional and computer methods used in the generation of the holographic couplers are described and diagrammed. The reconstruction geometries used are shown to be somewhat restrictive but substantially less rigid than their conventional optical counter-parts. Single and double hologram techniques are examined concerning their respective ease of fabrication and relative merits.

## REFERENCES | 43
I. INTRODUCTION

The use of optical fibers for the propagation of light emitted from a semiconductor laser (or laser diode, LD) has been an area of intense study for the past 5-10 years. Single mode LDs, in which only the fundamental mode is emitted, are proving to be a most attractive source for high data rate optical communication systems. When the output from a single mode LD is coupled into a single mode optical fiber, fiber dispersion (the spreading of the pulse shape due to differing propagation speeds for the modes in the fiber) is eliminated. Another benefit in using single mode optical fibers is that the emerging beam is well-behaved spatially, having a Airy disk far-field diffraction pattern.

In the past five years, a great deal of effort has been expended in decreasing the fiber transmission losses. With these losses now on the order of 0.2 dB per kilometer, emphasis has been turned to the large losses associated with coupling the LD output into the fiber (1-4).

The techniques currently employed for the coupling of LD light into a fiber consist of the following:

1. Butt-end joint: The fiber is cleaved so that its front face is perpendicular to the fiber core. It is then butted up against the LD.
2. Tapered fiber: Some of the fiber's cladding is etched off, by chemical or mechanical means, exposing the fiber's core. It is then positioned near the front facet on the LD.

3. Fiber-tip microlens: The tip of the fiber is melted and formed into a hemispherical lens. This end is then positioned such that the LD is at the lens' focal point.

4. Conventional optics: Lenses (typically 2 crossed cylindrical lenses) are placed in front of the LD to conform its output beam and focus it onto the fiber's core.

These techniques provide coupling efficiencies of less than 40%*. (The 40% figure has been reported in technical journal articles a laboratory results. A reproducible coupling efficiency of 20% is considered quite good (5)). The causes of this poor coupling efficiency are primarily attributable to the small acceptance angle of the fiber's 5 micron core (Numerical Aperture of about 0.2), and the large non-symmetric divergence of the LD beam (20 and 80 degrees parallel and perpendicular to the 0.7 micron by 10 micron LD lasing region. All of these techniques also result in very stringent alignment tolerances for the positioning of the fiber and any other optical elements, with respect to the LD front facet. Alignments of approximately 1-2 microns perpendicular and parallel to the LD front facet must be maintained for losses

*The coupling efficiency is given by the ratio of the amount of power launched into the fiber and the LD's output power.
of less than 1 dB. The spacing between the LD and fiber directly impacts coupling. The alignment tolerances in this case are in the 20 micron range for <1 dB loss.

II. WAVEFRONT CONVERSION COUPLER

A different approach to this problem is to examine the wavefronts of LD and fiber in the Fraunhofer diffraction region. At some plane in between the two devices these fields can be superimposed resulting in an interference pattern. Theoretically, if some sort of wavefront converting structure could be constructed and placed in this plane to effectively match the two "antennas" (the LD and the fiber), a coupling efficiency of 100% could result. This procedure would actually convert the wavefront diverging from the LD into the Airy disk far-field pattern of the fiber. This type of wavefront conversion falls into the general category of holography. So if a hologram representing the wavefront converting structure would be placed in this plane and then illuminated by the LD emission used to construct the hologram, all of the LD light impinging on the hologram would have its wavefront changed into the fiber's Fraunhofer diffraction pattern. The converted wavefront would then be totally accepted by the fiber core.

In considering diffraction from an aperture, the Fraunhofer region is defined as the distance, Z, from the aperture where the phase change over the aperture is assumed to be much less than 1 radian. If the aperture is considered to be rectangular with the maximum value of $x_1^2 + y_1^2 = (d/2)^2$ where d is the linear dimension of the maximum extent of the aperture, then this phase restriction implies:
Single-mode optical fibers have core diameters of 4-8 microns. LDs' maximum front-facet linear dimension is typically 10 microns. For the fiber and LD, the Fraunhofer assumption implies, assuming light with wavelength 830 nanometers.

\[
z_f \gg \frac{d_f}{\lambda} = 77 \text{ microns}
\]

\[
z_{LD} \gg \frac{d_{LD}}{\lambda} = 120 \text{ microns}
\]

Thus, if the hologram's positioning plane is chosen to be 150 microns away from the LD and fiber, the Fraunhofer diffraction condition is valid.

The amplitude distribution in the Fraunhofer diffraction pattern of the circular fiber core is the Airy disk pattern given by:

\[
U(r_o) = \exp (j k z) \exp \left( j \frac{K r_o^2}{2 z} \right) \left( \frac{K}{j 8 z} \right)^2 \left( \frac{2 J_1 \left( \frac{K r_o}{2 z} \right)}{\left( \frac{K r_o}{2 z} \right)} \right) \]

where \( l \) is the radius of the fiber core; \( r \) is the radius coordinate in the observation plane; \( Z \) is the distance from the aperture (fiber core) to the observation plane; and \( J_1 \) is the first order Bessel function.
With: \( r_0^2 = x_0^2 + y_0^2 \)

\[
U(x_0, y_0) = \exp(jKz) \exp \left( j \frac{K(x_0^2 + y_0^2)}{2z} \right) \left( \frac{K1}{jK} \right) \left[ a(x_0, y_0) \exp(j\psi(x_0, y_0)) \right]
\]

\[= A(x_0, y_0) \exp(j\psi(x_0, y_0)) \]

Similarly, the electric field a distance \( Z \) away from the LD's front facet is given by the Fraunhofer diffraction pattern for a rectangular aperture.*

\[
U(x_0, y_0) = \exp(jKz) \exp \left( j \frac{K(x_0^2 + y_0^2)}{2z} \right) \frac{1}{l_x l_y} \frac{1}{\lambda z} \frac{1}{\lambda z} \]

\[\times a(x_0, y_0) \exp(j\psi(x_0, y_0)) \]

(5)

where \( l_x \) is the linear dimension of the aperture in the \( x \) direction; \( l_y \) is the linear dimension in the \( y \) direction.

With the elements positioned as in Figure 1, the electric field at the plane \( P \) is given by the superposition of the two incident fields \( U_{LD} \) and \( U_f \).

\[U_p = U_{LD} + U_f\]

The resultant intensity distribution is: \( I_p = |U_p U_p^*| \)

*Equations (3) through (5) were derived assuming plane waves incident on the aperture. The field incident on the front facet of the single-mode LD (TE10 mode) is roughly planar, as in the case for a rectangular waveguide (6).
Figure 1. Component positions for superposition of the fields emanating from the LD and the fiber.
For the case of a monochromatic field:

\[ I_p = |U_{LD}(x_0, y_0)|^2 + |U_f(x_0, y_0)|^2 + 2 A(x_0, y_0)a(x_0, y_0)\cos(y(x_0, y_0)) - \phi(x_0, y_0) \]

Investigation of the terms yields:

\[ |U_{LD}|^2 = \left( \frac{1}{\lambda z} \right)^2 \sin^2 \left( \frac{1}{\lambda z} \right) \sin^2 \left( \frac{1}{\lambda z} \right) \]

(7)

\[ |U_f|^2 = \left( \frac{K_1}{8z} \right)^2 \left[ \frac{2J_1(\sqrt{\frac{x_0+y_0}{2z}})}{2J_1(\sqrt{\frac{x_0+y_0}{2z}})} \right]^2 \]

(8)

\[ 2A(x_0, y_0)a(x_0, y_0) = 2 \left( \frac{K_1}{8z} \right)^2 \left[ \frac{2J_1(\sqrt{\frac{x_0+y_0}{2z}})}{2J_1(\sqrt{\frac{x_0+y_0}{2z}})} \right] \left( \frac{1}{\lambda z} \right) \sin^2 \left( \frac{1}{\lambda z} \right) \sin^2 \left( \frac{1}{\lambda z} \right) \]

(9)

\[ \Psi(x_0, y_0) - \phi(x_0, y_0) = K_1(z + \frac{x_0^2 + y_0^2}{2z}) - K_2(z + \frac{x_0^2 + y_0^2}{2z}) \]

(10)
so,

\[
I_p = \left( \frac{1}{\lambda z} \right)^2 \text{sinc} \left( \frac{1}{\lambda z} x_0 \right) \text{sinc} \left( \frac{1}{\lambda z} y_0 \right) + \left( \frac{K_1}{8z} \right)^2 \frac{2J_1\left( \frac{K_1}{\lambda z} \right)}{2z} \frac{2z}{K_1/\lambda z + y_0^2} 
\]

+ \frac{K_1^2}{\lambda z} \frac{1}{\lambda} x y \text{sinc} \left( \frac{1}{\lambda z} x_0 \right) \text{sinc} \left( \frac{1}{\lambda z} y_0 \right) \frac{2J_1(A)}{A} 
\]

(11)

Figure 2 shows a cross section of \( I_p (x_0, y_0 = \pi \lambda z/21y) \) with \( \lambda = 830 \text{ nm}, z = 150 \text{ microns}, l_y = 0.7 \text{ microns}, l_x = 10 \text{ microns}, l = 6 \text{ microns.} \) These plots were generated by the computer program PF.FOR (listed in Figure 13).

III. COUPLING EFFICIENCY

The coupling efficiency, \( \eta_c \), can be decomposed into two principal terms; the transfer efficiency \( \eta_t \), and the intrinsic coupling efficiency \( \eta_i \).

\[
\eta_c = \eta_t \eta_i
\]

(12)

depicted in Figure 3.

The transfer efficiency involves the amount of input radiation absorbed by the hologram and its diffraction efficiency. It has been shown that for thick holograms transfer efficiencies of 85% are quite possible (7). The intrinsic coupling efficiency, \( \eta_i \), is the ratio of the light power accepted by the fiber to the power incident on the fiber's front facet. Thus \( \eta_i \)
Figure 2. Cross-sectional views of the intensity distribution at the plane P. 2a is the intensity pattern for the rectangular aperture; 2b is for the circular aperture; 2c is the combined intensity pattern on the $y_0$ axis; 2d is the combined pattern for $y_0^\infty$. 
Figure 3. Coupler efficiency defined as the product of the transfer and intrinsic coupling efficiencies.
depends on the accuracy of the hologram's imaging of the fiber's front facet. Leite and Soares (8) have shown that values of \( \eta_i \) above 85% can be achieved with only moderate difficulty.

Taking these reported values for the respective efficiencies, it should be possible to attain coupling efficiencies, \( \eta_c \), of approximately 75%.

IV. DOUBLE HOLOGRAM TECHNIQUE

The single element holographic method for coupling, while improving the coupling efficiency, still suffers, like the other coupling schemes, from the severe alignment tolerances. Unlike the other coupling schemes, alignment tolerances can be relaxed by using a slightly revised holographic method.

In this revised holographic method, the single hologram is split into 2 holograms (Figure 4). The first hologram is designed to convert the non-symmetric diverging LD emission into a plane wave. The second hologram is designed to convert an incoming plane wave into the fiber's far-field diffraction pattern (Airy disk). By utilizing the fact that holograms have all of the pattern's information stored in a small area, the alignment sensitivity, with respect to each other, of all four of the components (LD, holograms 1 and 2, and the fiber) is greatly decreased when compared to the sensitivity of the other coupling methods.*

*Lateral displacements between the coupler sections have virtually no consequence. However, tilt and rotation alignment become sensitive ((8) discusses methods for minimizing this sensitivity). Longitudinal displacement between the coupler and the source (LD or fiber) is believed to be no more sensitive than in the traditional techniques (20 microns for 1 dB loss) (4).
V. TWO-BEAM HOLOGRAPHIC FABRICATION

Fabrication of the holographic couplers consists of merely making the hologram(s). For the single element device, the holographic recording scheme employed is depicted in Figure 5a. The reconstruction (coupling) configuration is shown in Figure 5b. In the recording case, light emerges from the LD and interferes on the photographic film/plate $P$ with light from another laser focused at the spot where the fiber's end facet will be placed. The plate is then developed and reinserted into the system at plane $P$. When the hologram is illuminated by the LD radiation, $U_{LD}$, the fiber's coupling wave, $U_f$, is generated which propagates into the fiber.

In the case of the double holographic element technique, two holograms are generated. The recording procedure consists of using plane reference waves, $U_{r1}$ and $U_{r2}$, making complementary angles with the plane of the holograms in conjunction with the LD and fiber emissions (Figure 6). When hologram H1 is illuminated by the radiation from the LD, the plane wave $U_{r1}$ is generated. This wave, in turn, generates the coupling wave $U_f^*$ when it illuminates hologram H2.

VI. COMPUTER GENERATED HOLOGRAMS

A. INTRODUCTION

Another method of fabricating holograms is to use a computer and a plotter. In this method, the two-dimensional intensity distribution resulting

---

*Notice, in Figure 5A, that the fiber is positioned conjugate to where it will be when LD light is coupled into the fiber (Figure 5b).
Figure 5b. Reconstruction (coupling) method for the single holographic element coupler.
Figure 6. Recording scheme for the double hologram coupler.
from two beams interfering at some plane is calculated. This pattern is then converted into a form suitable for graphical representation by a discrete plotting device. A transparency is formed of the plot photographically or by some other method. The transparency then serves as the hologram.

Calculation of the intensity distribution resulting from the interference of two beams is a straightforward process. The diffraction patterns of the two radiation sources are known, or calculated, for the diffraction region in which they will be used (Fraunhofer or Fresnel). These fields are then propagated to the plane of interference and summed.* The intensity distribution of the interference plane is subsequently calculated.

At this point the hologram's intensity variation is known by the computer. This pattern must then be displayed in a form such that a transparency may be formed. The simplest method of displaying the pattern is to plot it on a hard-copy graphics device. The resulting printout may then be photographed to form the transparency.

The problem becomes one of how to accurately represent the intensity pattern, consisting of phase and amplitude information, by a discrete plotting device.

The most widely used method for displaying phase and amplitude information on a discrete plotting device is Lohmann's technique developed explicitly for computer generated holography (9). A binary (light-dark)

---

*This plane defines the position between the two devices where the hologram will be placed for reconstruction.
plotting scheme is used since it eliminates the need for generation of gray levels. Another benefit of the binary scheme is that in the photographic reduction step, development procedures are far less critical than for continuous-tone objects.

Lohmann's method utilizes the fact that the phase of the offset reference wave, also used for reconstruction, varies linearly along the x axis.*

Consider the system depicted in Figure 7 where a binary mask has been placed in the hologram plane. The mask is primarily opaque with holes centered on a regular grid at the sample points. The linear distance $\Delta x_o$ is chosen such that the phase of the offset reference wave increases along x by $2\pi$ radians through that distance. If two adjacent holes were spaced by $\Delta x_o$, then all of the light passed by the two holes will be of the same phase. If, however, one hole is displaced a distance $1.25 \Delta x_o$ from its adjacent one, as with holes C and B in Figure 7, then the light passed by that hole (C) will differ from the adjacent hole (B) by $2\pi + \pi/2 = 5\pi/2 = \pi/2$ radians. Destructive interference will occur between the light from these two holes. This technique of displacing the mask's holes with respect to one another, in accordance with the spacing $\Delta x_o$, and thereby encoding the phase of each sample point, is what Lohmann devised. Displacement of the holes is only performed in one direction thereby implying that there be constant phase along the orthogonal axis. The size of the hole corresponds to the amplitude of each sample.

Choosing the linear displacement, $\Delta x_o$, which corresponds to a $2\pi$ radian phase change of the reference wave establishes the recording, and thus the

---

*This procedure is applicable for a planes reference wave. This technique would then be suitable for the two-element holographic coupler system, but not for the single element system.
reconstruction, angle for the hologram. Figure 8 depicts a plane wave incident on a grid at an angle $\theta_1$. The path difference between the adjacent slits is given by:

$$[\Delta \text{PL}] = d \sin \theta_1$$

(13)

The corresponding phase difference is:

$$\phi = \left(\frac{2\pi}{\lambda}\right) d \sin \theta_1$$

(14)

We have chosen the linear distance $\Delta x_0 = d$ to correspond to a $2\pi$ radian phase difference. So:

$$2\pi = \frac{2\pi}{\lambda} \Delta x_0 \sin \theta_1$$

(15)

The recording and reconstruction angle is then given by:

$$\theta_1 = \sin^{-1} \left(\frac{\lambda}{\Delta x_0}\right)$$

(16)

The linear displacement distance, $\Delta x_0$, is chosen based on, among other things, the resolution of the plotting device, its maximum allowable plotting size, and the number of discrete points in the sample.

B. FOURIER TRANSFORM HOLOGRAMS

Lohmann first examined Fourier transform holograms (i.e. holograms of the Fourier transform of the object rather than of the object itself) (9, 10). 

20
Figure 8. A plane wave incident on a grid.
The method used to generate the hologram relies on the plotting scheme described earlier. The procedure for producing a computer generated Fourier transform hologram is the following. The object, if it is represented by a continuous function, is decomposed into discrete samples so that a FFT may be performed on it numerically. This sampling interval should be chosen in accordance with the Whittaker-Shannon sampling theorem thereby ensuring that the maximum amount of information about the object is retained. The Fourier transform of the object is computed using a discrete FFT routine. Each sample of the Fourier transform of the object is encoded via the Lohmann method. The plot is photographically reduced, negated,* and reconstructed. Reconstruction is accomplished by using a lens to perform an optical Fourier transform of the image formed by the hologram (Figure 9).

C. EXPERIMENT - A COMPUTER GENERATED BINARY FOURIER TRANSFORM HOLOGRAM

A binary computer generated Fourier transform hologram of the two-dimensional character P was produced. A Digital Equipment Corporation VAX-11/780 computer with an associated Trilog printer/plotter was used to perform the computations and plotting. The procedure followed in fabricating the hologram is that outlined earlier. The character was defined in a discrete array of dimensions 64 x 64. By defining the object discretely, the need for accurate sampling of a continuous function was avoided. The Fourier transform of the object was performed by the IBM scientific support FFT subroutine HARM.

*The aperture representing the phase and magnitude of each sample is darkened in. The use of the photographic negative as the hologram reverses the plotted contrast thereby making only the aperture transparent.
Figure 9. Reconstruction system for a Fourier transform hologram.
Each element in the Fourier transformed object has its phase and magnitude encoded as an aperture within a square cell. The height of the aperture is proportional to the magnitude of the sample, while the position of the aperture within the cell is determined by the sample's phase. The size of the square encoding cell, along with the plotter's resolution, dictate the quantization levels for the phase and magnitude of the sample. Figure 10 depicts two adjacent cells in which the phase and magnitude of two adjacent sample points of Fourier transform of the object will be plotted. The object was represented by a 64 x 64 element array. The Trilog plotter can plot 1320 points across its 30.48 cm (12 inch) plotting region. The plotter's resolution is therefore 0.0231 cm. At this point, it would be possible to quantize the phase of each element into 20 parts (1320/64 = 20.62). While this would allow very good phase representation, the aperture would have a width of 0.0231 cm. This would result in a very dim image because of the narrow aperture. The phase quantization level was chosen as 6 so that each phase region would be represented by 3 pixels.* The aperture width was thus 0.0693 cm. The magnitude quantization level was not limited by the plotter, only by the length of plotting paper available. The magnitude quantization was chosen to be 7. Thus the height of the aperture could range from 0.0 to 0.1386 cm. The linear extent of the square aperture cell (Figure 10) was 0.1386 cm. Since the linear extent of the square cell corresponds to $\Delta x_o$, this implies that $\Delta x_o = 0.1386$ cm. $\Delta x_o$ corresponds to a $2\pi$ radian phase change so by equation (16) we see that the recording and reconstruction angle, for He-Ne laser light ($\lambda = 6328$ A) is 0.0262 degrees.

*While this coarse phase quantization results in some degradation in the reconstructed image, the image brightness was deemed more important at this time.
Figure 10. Aperture cells for object representation. $\Delta X_o$ corresponds to a $2\pi$-radian phase change.
The method for encoding the object's information is to calculate the phase and magnitude of the Fourier transformed object and see what quantization bin each element's values fall into. The phase quantization level of 6 means that the bins span the phases $0 - \pi/3$, $\pi/3 - 2\pi/3$, $2\pi/3 - \pi$, $\pi - 4\pi/3$, $4\pi/3 - 5\pi/3$, $5\pi/3 - 2\pi$. The object element being plotted has its phase scanned and the appropriate phase bin noted. The maximum magnitude in the entire object array is found. This point will have its entire aperture filled in and is therefore scaled to the magnitude quantization level of 7. The magnitude of each object is then scaled to the maximum magnitude value. The magnitude of each element is examined to see how much of the aperture should be filled in. The appropriate magnitude quantization amount is noted. By proceeding through the entire object array, the plot array is determined and plotted.

Figure 11 shows the original object plotted on the phase-magnitude grid. Figure 12 shows the Fourier transform of the object plotted on the phase-magnitude grid. Notice in Figure 12 that the sizes and locations of the apertures differ for different object points.

Initial plotting of the Fourier transformed object showed that the FFT has too large of a dynamic range for quantization into only seven levels. Therefore, the logarithm of the FFTed object was used for magnitude quantization. To avoid arguments of zero, a one was added to each value in the FFT object. The side effect of this operation is to enhance edge detail in the reconstructed image, as low frequencies are suppressed with respect to higher ones (11).
A listing of the computer program, CGHBLACKP FOR, used to generate the binary plots is given in Figure 14.

VII. CONCLUSIONS

The use of holographic couplers for LD - fiber systems results in reduced alignment tolerances and higher efficiencies than the traditional techniques used in coupling.

Fabrication of the couplers could be achieved via conventional holographic manufacturing techniques or by the computer generated approach. While both techniques have their advantages, overall the conventionally fabricated hologram is the better of the two when used as coupling devices. The diffraction efficiency from a conventional hologram is higher than from a binary computer generated hologram (12). Considerable higher resolution is obtainable in the conventional fabrication process than in the computer generated process. Holographic films have resolutions of 1250 lines/mm (0.8 microns) (13) while plotting devices resolution is typically 200 microns.

While binary computer generated holograms can be fabricated for non-existant devices, a mathematical description of the object is necessary and may be hard to implement on a computer.

Each holographic coupler is fabricated for the particular LD - fiber pair with which it will be used. Spatial variations in the LD output beam change from LD to LD and therefore may not match the recorded LD beam pattern.
There are some limitations in the use of holographic coupling devices. Recording film sensitivity is quite low in the 830 nm wavelength region. This effect requires relatively long exposure times over which the recording system must remain very stable. Fluctuations in the LD output beam due to temperature instability will introduce a mismatching factor into the coupling system. The hologram was developed for one particular LD beam pattern; when the reconstruction beam pattern differs from the recorded beam pattern, LD - fiber matching will degrade.

Overall, the advantages of holographic couplers over the traditional couplers for LD - fiber systems warrant experimentation into the hologram's practical usefulness in coupling.
This program generates a Fourier transform plot suitable for conversion into a hologram following photographic reduction. The TriLog printer/plotter is used for generation of the binary plot. (CGHblackP plots only black characters. the colored phase-magnitude grid is not generated in this program).

type *, enter 0 to plot original, f for FFT, i for Finv(F), accept 60, 80, 92
    format(1x,1l)
     ierr=0 !init HARM error flag
If set $\neq 1$, have HARM generate its own internal sine and cosine tables for the FFT.

If $g(x, eq. 'o')$, go to 85. If requested, don't do the FFT.

Call HARM(a, m, inv, s, ifset, ierr) -- SSP FFT routine.

If(ierr, eq. 0), go to 83.

Type $x$, FFT error code $x$, ierr.

If $g(x, ne. 'l')$, go to 85. Don't perform FInv unless requested.

If set $= 1$, have HARM generate its own internal sine and cosine tables for F inverse.

Call HARM(a, m, inv, s, ifset, ierr) -- SSP FFT routine.

If(ierr, eq. 0), go to 85.

Type $x$, inverse FFT error code $x$, ierr.

determine the magnitude and phase of each object element.

85

do 100 $i=1, 64$
do 100 $j=1, 64$

$amag=\text{fabs}(a(i,j,1))$

If(\text{real}(a(i,j,1)).ne.0.0), go to 90.

If the real part equal 0? $x=pi/2$.

$y=\text{imag}(a(i,j,1))$

$\text{sign}(x, y)$

The phase $= pi/2$ times the sign (+ or -) of the imaginary part. (If the real component of this number $\neq 0$, then the phase angle is + or - $pi/2$. If the imaginary part is negative then the phase angle is negative.

go to 95.

90

$\text{sign} = \text{atan2}(\text{imag}(a(i,j,1)), \text{real}(a(i,j,1)))$

Determine the phase angle.

95

$b(i, j) = \text{complex}(amag, \text{apha})$

Put the magnitude and phase into the real and imaginary parts of $b$.

100

Type $x$, do you want to store the mag-phase data (y or n)?

Accept 88, go.

If $g(x, ne. 'l')$, go to 104.

Do 110 $i=1, 64$

Do 107 $j=1, 64$

$zmax=\text{real}(b(1, 1))$

Real part (magnitude)

$zpha=\text{imag}(b(1, 1))$

Complex part (phase)

Write (9, 1003) $i, j, zmax, zpha$

Format (b', $i, $j, $zmax) = ', e15.8, x, e15.8)

1005

107

110

Find the maximum magnitude value in the $b$ array.

104

$zmax = \text{log}(\text{real}(b(1, 1))+1.0)$

Make the 1st element the largest (start). Take logarithm because FFT has too large of a dynamic range.

Do 120 $i=1, 64$

Do 120 $j=1, 64$

Check every element.

$z = \text{log}(\text{real}(b(i, j))+1.0)$

$zmax = \text{max}(z, zmax)$

Use the maximum value function for the comparison.

This program calculates the intensity for two electric fields interfering at a plane a distance \( z \) between them. Fields are calculated for a rectangular aperture and a circular aperture. These fields are then combined at the holographic (interference) plane. The resulting intensity pattern is subsequently scanned for its maximum value. The output data is scaled such that the maximum value will just saturate the output plot. Plotting is performed on a DEC VT-11 display and a Versatec Printer/Plotter.
