I. INTRODUCTION

The goal of this grant was to study lasers, laser devices, and novel uses of lasers to study physical phenomena. The active projects included the development of a tunable, narrowband XUV light source and its application to the spectroscopy of core-excited atomic states, and the development of a new technique for picosecond time-resolution spectroscopy of fast photophysical processes. These projects are described in more detail in the following sections.
II. SUMMARY OF RESEARCH

A. PICOSECOND MEASUREMENTS USING THE OPTOACOUSTIC DETECTION IN LIQUIDS WITH AN IMPROVED SAMPLE CELL

Staff: Jean-Marc Heritier
Research Supervised by Professor A.E. Siegman

Conventional picosecond spectroscopy uses either relatively complex detection apparatus (streak cameras, etc.) or stroboscopic two-pulse techniques to measure fast relaxation rates, generally in liquid or solid samples. Conventional photoacoustic spectroscopy, on the other hand, employs slowly chopped or pulsed light sources to measure weak absorptions in liquid, solid or gaseous samples by using the deposited heat energy to generate a detectable pressure wave. The first technique thus provides a powerful tool for measuring fast phenomena, while the latter is a simple, inexpensive and yet very sensitive technique of spectroscopy.

The work supported by this grant and which has been described in previous reports, has led to a new technique for accomplishing picosecond spectroscopy using the photoacoustic detection mechanism. In this two-pulse method, the photoacoustic signal is recorded as a function of delay between two ultrashort laser light pulses.

To carry out these experiments, we have designed and built a new photoacoustic cell for liquid samples which focused the pressure waves onto the receiving transducer for increased sensitivity. We found the ultimate sensitivity of this cell to be extremely good, so that an absorbed energy of \(~3\) nJ could be detected by integration over 10 shots with a signal to noise of \(1\). While developed especially for these picosecond measurements, this cell may have wider uses in photoacoustics generally.

Extensive analysis of the pressure wave produced inside the liquid cell also led us to a complete and quantitative understanding of both the thermal and electrostrictive contributions to the pressure wave, and allowed us to predict the behavior of the photoacoustic cell under picosecond excitation.

Picosecond photoacoustic experiments on different dyes have been performed. We measured the excited state lifetimes of several molecular dyes with this technique. For the first time, a good measure of the excited-state-absorption cross
section at 1.064 μm of Rh6G and RhB is reported. Rotational effects have also been observed with Rh6G in heavy water and can be explained very well with a combined lifetime and rotational diffusion relaxation process.

We thus believe that the combined picosecond pulse plus photoacoustic detection method demonstrated in this research will become a useful and effective method for picosecond spectroscopy. This approach should be particularly applicable for measurements on weakly absorbing systems (such as dilute or expensive samples); for systems where excited-state fluorescence is not available as a detection mechanism; and for observations of weakly absorbing excited states in liquids or in solids. Much shorter laser pulses than used in our experiment are now available, and can equally well be used to gain greater time resolution. The use of more stable cw mode-locked lasers with greater pulse uniformity and higher repetition rate would substantially improve the signal averaging in the experiments, and further improvements in the cell design and electronics are also possible. The use of a tunable mode-locked dye laser would permit the determination of complete excited-state absorption spectra. Difficulties do arise, however, when the probe beam wavelength is short enough for the ground state absorption to become important.

To our knowledge, this is the first time that rotational relaxation effects have been observed on the excited-state absorption in organic dyes. These observations give useful information about the relative dipole orientation for the two absorption processes.

The research under this grant has resulted in a number of publications, including a Ph.D. dissertation just completed by J-M. Heritier.
B. DEVELOPMENT OF A TUNABLE, NARROWBAND XUV LIGHT SOURCE

Research Supervised by
Professors S.E. Harris and J.F. Young

The goal of this project is the development of a new light source in the extreme ultraviolet spectral region. The source is based upon the scattering of a tunable visible dye laser off an excited metastable atomic population (spontaneous anti-Stokes Raman scattering). The scattered photons have an energy equal to the sum of the storage energy and of the incident laser photon energy, are synchronous in time with the laser, and have a very narrow bandwidth determined by the convolution of the laser bandwidth and the Doppler width of the storage state.

Initial experiments have been made using helium as the storage species, producing radiation in the region of 54 nm with a resolution of 1.3 cm⁻¹. Tunability, however, was limited by the moderate brightness of the source and signal-to-noise considerations. The major efforts of the past year have concentrated on improving the source through a combination of increased storage population levels, improved collection geometry, and improved detection. We have also considered the use of other storage species in order to cover different spectral regions. These efforts have been quite successful, and the results are presented in a paper titled “Spontaneous Raman Scattering as a High Resolution XUV Radiation Source,” which is to be published in a Special Issue of the Journal of Quantum Electronics devoted to the generation and use of XUV and soft x-ray radiation. A preprint of this paper is included as Appendix II.

ABSTRACT

We report experimental results on picosecond spectroscopic measurements of excited-state cross sections, polarization properties, and lifetimes in organic dye solutions using a new technique for photoacoustic detection of the total photoacoustic impulse produced by two ultrashort optical pulses with variable time delay between them. The photoacoustic detection technique reported here appears to be a promising new way to observe weak excited-state cross sections, or to perform picosecond lifetime measurements in weakly absorbing and/or nonfluorescing optical systems.
PICOSECOND MEASUREMENTS
USING PHOTOACOUSTIC DETECTION

Jean-Marc Heritier and A. E. Siegman

I. Introduction

Picosecond spectroscopy using ultrashort laser light pulses has now become an effective and successful tool for the measurement of ultrafast relaxation rates in many different physical systems [1]. At the same time, photoacoustic spectroscopy [2], in which one detects the thermo-acoustic signals produced by absorption of a laser beam in an absorbing sample, has become a similarly successful tool for measuring weak absorption lines in a variety of physical systems.

In an earlier publication [3] we proposed to combine the time resolution of picosecond spectroscopy with the simplicity and sensitivity of photoacoustic detection, by using a photoacoustic cell as the detection mechanism for picosecond pulse experiments. Photoacoustic detection by itself of course cannot achieve sub-nanosecond or picosecond time resolution. By observing the integrated photoacoustic response to two picosecond pulses with varying time delay, however, using a stroboscopic type of approach, one can measure fast relaxation processes with time resolution limited only by the optical pulse widths, even though the photoacoustic detection mechanism is much slower.

We have now carried out a preliminary experimental demonstration of this technique, with results which we report in this paper. Significant biological measurements made using a very similar technique have also been reported in the past year by Bernstein, Rothberg, and Peters [4]; and a similar type of time-resolved photoacoustic polarization spectroscopy has also been independently suggested by Hänsch [5].

In earlier papers we have already described an elliptical photoacoustic cell design which we developed for use in these experiments [3], and have also given an analysis of the acoustic impulse developed in a cylindrical geometry by a picosecond optical pulse (or a pair of closely spaced such pulses) [6]. In the present paper we first develop a simple theory based on rate equations to predict the photoacoustic signal behavior that will be measured versus inter-pulse delay in a stroboscopic
two-pulse experiment. We analyze both the case where the two light pulses have the same wavelength and the case where they have different wavelengths, and show the latter situation to be much more favorable.

We then present experimental results obtained with several different dyes excited with short pulses at 532 nm and 1.064 μm wavelengths from a mode-locked Nd:YAG laser. These results allow us to measure both the $S_1$ lifetime and the excited-state absorption cross-section at 1.064 μm of these dyes. Some rotational diffusion effects have also been experimentally demonstrated in a preliminary fashion for Rh6G using parallel or crossed polarizations for the two light pulses.

II. Theory

We propose to study molecules having a cross-section $\sigma_1$ from the ground state $S_0$ to $S_1$ at the wavelength $\lambda_1$ of a first or excitation light pulse, and a cross-section $\sigma_2$ from the excited state $S_1$ to higher levels $S_{1}^{*}$ or $S_n$ at the wavelength $\lambda_2$ of a second or probe pulse, as shown in Fig. 1. The special case where the two pulses have the same wavelength is also treated separately in Appendix A.

To analyze this system we start with six levels so as to describe accurately the saturation effects, but immediately simplify the algebra by assuming that the nonradiative decay rates $\gamma_{64}, \gamma_{32}$ and $\gamma_{10}$ are infinitely fast. We also assume that the decays from level 4 to levels 3 and 2 are completely nonradiative; a finite fluorescence quantum efficiency could be readily incorporated here, thereby reducing the photoacoustic signal generated along the 5→2 decay path. Similarly, the decay from level 2 to level 1 is assumed to be completely fluorescent. The frequency $\omega_{10}$ would have to be adjusted to account for any nonradiative part of the 2→0 decay.

The relevant rate equations under these conditions are reduced to

$$\frac{dN_4}{dt} = \left(\frac{\sigma_2 I_2}{\hbar \omega_2}\right)N_2 - \gamma_4 N_4$$ \hspace{1cm} (1)

and

$$\frac{dN_2}{dt} = \left(\frac{\sigma_1 I_1}{\hbar \omega_1}\right)N_4 - \left(\frac{\sigma_1 I_1}{\hbar \omega_1} + \frac{\sigma_2 I_2}{\hbar \omega_2}\right)N_2 + \left(\frac{\sigma_1 I_1}{\hbar \omega_1}\right)N$$ \hspace{1cm} (2)
where $I_1$ and $I_2$ are the instantaneous intensities at $\lambda_1$ and $\lambda_2$; $N = N_0 + N_2 + N_4$ is the total population; and $\gamma_4 = \gamma_4 + \gamma_4$ is the total downward decay rate from level 4. Equations (1) and (2) can be solved easily for constant intensities $I_1$ and $I_2$ to give

$$N_4(t) = \frac{N \sigma_2 I_2}{D} \frac{\sigma_2 I_2}{\hbar \omega_2} \exp (\lambda_a t) + B \frac{\sigma_2 I_2}{\hbar \omega_2} \exp (\lambda_b t)$$  \hspace{1cm} (3)

and

$$N_2(t) = \frac{N}{D} \frac{\gamma_4 + A(\gamma_4 + \lambda_a) \exp (\lambda_a t) + B(\gamma_4 + \lambda_b) \exp (\lambda_b t)}$$  \hspace{1cm} (4)

where $D = \gamma_4 + \sigma_2 I_2/\hbar \omega_2 + \gamma_2 \gamma_4 \hbar \omega_1/\sigma_1 I_1$. The eigenvalues $\lambda_a$ and $\lambda_b$ with signals present are given by

$$\lambda_a, \lambda_b = -\frac{1}{2}(\gamma_2 + \gamma_4 + \sigma_1 I_1/\hbar \omega_1 + \sigma_2 I_2/\hbar \omega_2) \pm \frac{1}{2} \sqrt{\Delta}$$

where

$$\Delta = \left( \gamma_4 - \gamma_2 + \frac{\sigma_2 I_2}{\hbar \omega_2} - \frac{\sigma_1 I_1}{\hbar \omega_1} \right)^2 + \frac{4 \gamma_2 \sigma_2 I_2}{\hbar \omega_2}$$

and the constants $A$ and $B$ depend upon initial conditions.

We assume that the nonradiative relaxation energies are immediately transferred into heating of the surrounding medium. Hence at any instant $t$ the amount of heat energy $H$ deposited in the medium per unit volume and per unit-time will be

$$\frac{dH}{dt} = \left[ \frac{\sigma_1 I_1}{\hbar \omega_1} N(t) + \left( \frac{\omega_{51} \gamma_2}{\omega_3} - \frac{\sigma_1 I_1}{\hbar \omega_1} \right) N_2(t) + \left( \frac{\omega_{42} \gamma_4}{\omega_3} - \frac{\sigma_1 I_1}{\hbar \omega_1} \right) N_4(t) \right] \hbar \omega_3$$  \hspace{1cm} (5)

In order to simulate a two-pulse sequence, we now assume that the light intensity at wavelength $\lambda_1$ is on from $t = 0$ to $t = \tau_1$; the system is left to partially relax from $t = \tau_1$ to $t = \tau$; and then the light intensity at wavelength $\lambda_2$ is on from $t = \tau$ to $t = \tau + \tau_2$. At time $t = 0$, before the $\lambda_1$ pulse arrives, all the dye population is in the ground state, i.e., $N_0 = N$. Since the time scale of the whole process,
successive illumination plus relaxation, is less than the acoustic propagation time across the beam (~20 ns at most compared to 50 ns at least) [6], the acoustic signal will be proportional to the total heat deposited during the two-pulse excitation. We can write separate solutions for two cases of experimental interest, depending on whether the decay rate $\gamma_{21}$ of the first excited singlet level is slow or fast compared to the pulsewidths:

1) If we assume that the pulses are short and intense, so that $\gamma_{21} \tau \ll (\sigma_1 E_1/\hbar \omega_1)$, and that $\gamma_4$ is very fast so that $\gamma_4 \tau_2 \gg (\sigma_2 E_2/\hbar \omega_2)$, then the photoacoustic signal voltage $PAS$ as a function of pulse delay $\tau$ becomes

$$PAS = KN[1 - \exp(-E_1/E_{1S})][\omega_{32} + \omega_{10} + (E_2/E_{2S})\omega_{52} \exp(-\gamma_{21} \tau)]$$

where $E_1$ and $E_2$ are the energy fluences of the two light pulses; $E_{1S}$ and $E_{2S}$ are the saturation energies $\hbar \omega_1/\sigma_1$ and $\hbar \omega_2/\sigma_2$; and $K$ is a constant factor that accounts for the cell geometry and the detector sensitivity.

We see that the photoacoustic signal is made up of a constant background, caused by the $E_1$ pulse and independent of the pulse delay, plus an exponentially decaying part proportional to $\sigma_2 E_2$. The ratio of these two quantities will be

$$R = \frac{\sigma_2 E_2}{\hbar (\omega_{32} + \omega_{10})}$$

where we used the fact that $\omega_{52} = \omega_2$. This ratio can be measured experimentally and thus used to determine the excited-state absorption coefficient $\sigma_2$. Note that this ratio will not depend upon the light pulse energy $E_1$ at $\lambda_1$, which can be weak or on the contrary can completely saturate the ground state absorption. In either case, the photoacoustic signal will be proportional to the excited state initial population $N[1 - \exp(-E_1/E_{1S})]$ created by the light pulse at $\lambda_1$, but the ratio $R$ will be independent of $E_1$.

2) When $\gamma_4$ is very fast so that $\gamma_4 \tau_2 \gg E_2/E_{2S}$ and $\gamma_4 \gg \gamma_{21}$, another situation of interest is obtained if $\gamma_{21}$ is very fast so that $\gamma_{21} \tau \gg 1$ and $\gamma_{21} \tau_2 \gg 1$. In this case the photoacoustic signal again is the sum of a constant background plus a delay dependent term which decays as $\exp(-\gamma_{21} \tau)$. The ratio of these two terms
for zero delay ($\tau = 0$) can be found to be:

$$R = \frac{1}{\gamma_{21}^2 \tau_1 \tau_2 \hbar (\omega_{32} + \omega_{10})} \frac{\sigma_2 E_2}{\gamma_{21}}$$

(8)

The ratio $R$ found for slow decay of the excited state (Eq. 7) is now divided by the dimensionless factor $\gamma_{21}^2 \tau_1 \tau_2$ when $\gamma_{21}$ is large. Small ratios $R$ will therefore be measured if the absorption cross-section $\sigma_2$ is small and/or if the decay rate of the excited state $\gamma_{21}$ is fast.

The case where the two pulses have the same wavelength $\lambda_1$ is treated separately in Appendix A.

III. Experimental Results

A. Single-Pulse Saturation Experiments

In order to verify that saturation and excited-state absorption effects could in fact be observed, we first carried out a small number of experiments with our apparatus using only one pulse at 532 nm, and recording the photoacoustic signal along with the transmitted energy for different values of the incident energy. The theory for this case is developed in Appendix A. These experiments used 80 ps long light pulses with total energy of up to 5 $\mu$J maximum focused to a spot size $w_0 = 100$ $\mu$m in our elliptical photoacoustic cell. A similar setup used for two-pulse experiments is described in detail later.

Some typical early single-pulse results obtained with the dye rubrene in benzene are shown in Fig. 2. We observe that for input energies above the saturation energy $E_{1S} = h\omega/\sigma_1 \approx 7.7$ mJ/cm$^2$ that can be calculated using the published [7] value for $\sigma_1$ of rubrene (42$\times$10$^{-18}$cm$^2$ at 532 nm), the photoacoustic signal begins to increase in more than linear fashion, even though the transmitted optical energy increases in essentially linear fashion and shows no strong evidence for saturation of the $S_0 \rightarrow S_1$ transition.

We interpret these results as arising from partial saturation of the $S_0 \rightarrow S_1$ transition, followed by excited-state absorption of the 532 nm pulse from the $S_1$ level. Absorption from the excited state would be expected to produce relatively more photoacoustic signal than absorption from the $S_0$ ground state, both because
nonradiative relaxation rates from higher levels are expected to be stronger than from the largely fluorescent $S_1$ level, and because the energy gap involved is larger. Note that more careful measurements of this type of data using a more stable laser could permit measurements of saturation intensities that are difficult to see optically, as well as possible measurements of excited state cross sections, without the use of any optical detector. A similar approach has also been used earlier, with much longer pulses, by Razumova and Starobogatov [8].

Similar nonlinearities in the photoacoustic response versus input pulse energy were also observed for Rhodamine B in ethanol and for the food dye Red #40 in ethanol. For these solutions, however, the photoacoustic signal per unit input energy decreased with increasing input energy fluence. We interpret this as arising from saturation of the ground state absorption, without producing excited-state absorption at the same wavelength. However, further detailed information was difficult to obtain from these preliminary results.

In order to complement these preliminary results, a two-pulse experiment with two 532 nm pulses was attempted on a solution of rubrene in benzene. However, this experiment was not successful in exhibiting a delay dependent photoacoustic signal. The expected contrast between the constant background and the exponentially decaying part of the signal was only predicted to be about $8 \times 10^{-2}$, based on the nonlinearity of the photoacoustic signal versus input energy curve of Fig. 2 and the analysis of Appendix A. Furthermore, the 16.5 ns excited-state lifetime of rubrene [7] is so long that only partial excited-state relaxation could be reached with our 10 ns delay line. The data was therefore hidden in long term noise variations and delay line misalignment problems.

B. Two-Pulse Experimental Apparatus

As was pointed out earlier, a two-pulse experiment using two different wavelengths $\lambda_1$ and $\lambda_2$ can have a much better contrast than a single-wavelength experiment. Such an experiment should yield important information on the short-lived excited states of various dyes and their absorption cross section at the probe wavelength $\lambda_2$.

The setup used to demonstrate this experimentally is shown in Fig. 3. A cw-pumped, repetitively Q-switched and mode-locked Nd:YAG laser produces bursts
of about twenty mode-locked pulses that are ~100 ps in duration and separated from each other by the roundtrip time $T \approx 1.8$ ns, at an adjustable repetition rate of 30 to 100 bursts per second. A LiNbO$_3$ Pockels cell selects the most intense (50 $\mu$J) pulse of each burst, which is then frequency-doubled in an angle-tuned C$^4$A crystal. The green radiation is then separated from the remaining infrared and sent through a mechanical delay line controlled by a computer.

The infrared beam is sent along a separate optical path with fixed delay, and both beams are focused into the photoacoustic cell from opposite sides to the same spot size of ~70 $\mu$m. The resulting photoacoustic signal is preamplified inside the shielded housing that contains the photoacoustic cell, then amplified and sent to an 8-channel Sample and Hold electronic device. Three photodiodes $D_3$, $D_2$, and $D_1$ monitor respectively the energy of the green pulse ($E_{532}$), the energy of the infrared pulse ($E_{1064}$) and the energy in the green produced by a nonsaturated LiIO$_3$ crystal which doubles a small part of the original infrared pulse ($E_{\text{NS532}}$). These signals are also sent to the Sample and Hold device and the computer reads them along with the photoacoustic signal after each laser pulse.

Monitoring of the effective pulse width as obtained by $E_{1064}^2/E_{\text{NS532}}$ on each shot is necessary to monitor the shot-to-shot operation of our somewhat unstable single-pulse selector. The laser repetition rate of 40 Hz in most experiments is limited largely by the data acquisition process. Mechanical shutters, controlled by the computer, are located in the optical path of each beam. These allow us to find the delay-independent part of the photoacoustic signal due to the 532 nm beam alone, caused primarily by ground state absorption in the dye under study; or the delay-independent component due to the 1064 nm beam alone. Since the 1064 nm wavelength is not significantly absorbed by the ground state in the dyes we studied, the latter signal comes primarily from absorption of the IR wavelength in the solvents employed.

The spatial alignment of the two beams is realized by first removing the photoacoustic cell, then positioning a 50 $\mu$m pinhole at the focal spot of one beam and optimizing the transmission of the other. The 532 nm beam in the delay line is collimated with a spot size $w = 1.3$ mm and a Rayleigh range $z_R = 10$ m which ensures that no defocusing will take place when the delay line increases the optical path by a maximum of 3 m. A typical experiment lasts from 5 minutes to 1 hour.
and the data, immediately displayed on the computer console, are also permanently stored for later analysis.

C. Two-Pulse Experimental Results

Our first experiment was performed on Rhodamine 6G dye dissolved in ethanol with a molarity of $1.8 \times 10^{-9} \text{M/l}$ and an absorption coefficient $\alpha = 0.43 \text{ cm}^{-1}$ at 532 nm. Figure 4 shows the delay-dependent photoacoustic signal produced by both the 532 nm and 1064 nm pulses arriving in the sample. As expected, this signal is very close to zero when the delay is negative because the 1064 nm pulse, arriving before the 532 nm pulse, does not see any excited state, and therefore the two pulses are completely decoupled. For positive delays, however, the signal is large and proportional to the exponentially decaying excited state population. When the delay is larger than about 4.8 ns, a second jump in the photoacoustic signal is observed. This is due to the (undesired) transmission by the Pockels-cell pulse selector of a second, less intense pulse after the main one. When the probing pulse delay is larger than the roundtrip time $T$ of the laser oscillator, the main 1064 nm pulse is able to probe additional new excited state population created by this second pulse.

The bottom of Fig. 4 shows the same data plotted on a logarithmic scale. It verifies that the decay is exponential with a lifetime $\tau = \gamma_{21}^{-1} \approx 3.7 \pm 0.2 \text{ ns}$, in good agreement with the published data [7].

The delay-dependent signal shown in Fig. 4 rides on top of a delay-independent signal produced by the two pulses acting separately. The background due to the $S_0$ to $S_1$ absorption of the 532 nm pulse alone is approximately twice as large; and the background due to the solvent absorption of the 1064 nm pulse is about 10 times larger.

The complete photoacoustic signal, including the constant background part due to the ground state absorption in Rh6G of the 532 nm pulse, was also used to compute the ratio $R$ given by Eq. (7). The total energy at 1064 nm in each pulse was 15 $\mu$J. Assuming $\omega_{32} + \omega_{10}$ to be the difference between the 532 nm frequency and the frequency of a fluorescence photon at 500 nm, the excited state cross section can be easily calculated, and is given in Table 1.
We also studied a 3.2 × 10⁻⁶ M/ℓ solution of Rhodamine B in ethanol with an absorption coefficient of α = 0.36 cm⁻¹ at 532 nm. Figure 5 shows the data obtained for this dye. The same comments that were made for Rhodamine 6G apply to this experiment. The decay time is found to be \( \tau = 2^{-1} = 3.30 ± 0.15 \) ns, in good agreement with the value of 3.2 ns published in Ref. [7], but a bit too long compared to the value of 2.9 ns published in Ref. [9].

The excited-state cross section was again deduced from the ratio of the exponential portion to the constant background due to the 532 nm pulses alone, assuming again that the 2 → 1 decay is purely fluorescent at 590 nm. The resulting excited-state cross sections are given in Table 1.

Finally we did the same kind of experiment with the food dye Red #40 in heavy water. (Heavy water was used to minimize the background absorption of the 1.064 μm pulses). No delay-dependent signal could be seen above the background noise fluctuations in this experiment, however. It is believed the main reason for this is the extremely fast and mainly nonradiative decay \( \gamma_{21} \) in this dye (almost no fluorescence is emitted from the sample when illuminated by 532 nm pulses). Assuming \( \omega_3 + \omega_1 \) is the frequency of radiation of 532 nm wavelength and taking \( \tau_1 = 80 \) ps, \( \tau_2 = 100 \) ps, an upper limit for the ratio \( \sigma_2 / \gamma_{21}^2 \) can be found using Eq. 8, as given in Table 1.

Each excited-state cross section given in Table 1 is the result of several runs and the quoted uncertainty is mainly due to experimental errors including beam misalignment. (If the 1064 nm pulse does not probe the exact region excited by the 532 nm pulse, the absorption will be reduced and the cross section will be underestimated). There are of course also uncertainties which arise from the fact that the real molecular system may be more complex than our analytical model.
Our data does not agree well with the excited-state cross section of \( \sigma_2 \approx 2.2 \times 10^{-17} \text{ cm}^2 \) for Rhodamine 6G at 1064 nm given in Ref. [10]. These quite different experiments may very well be probing different properties of the excited state, and thus agreement is not necessarily to be expected.

### D. Rotational Relaxation and Polarization Experiments

It is well known [11,12,13] that an ensemble of randomly aligned molecules, such as Rhodamine 6G in solution, when excited by a linearly polarized light beam, will exhibit an anisotropy in its excited-state absorption. This is due to preferential excitation of those molecules whose transition dipole moment is oriented along the excitation \( E \) field. If a light pulse is sent to probe the excited state population immediately following a linearly polarized excitation pulse, this probe pulse will see a different absorption if its polarization is parallel to the excitation beam polarization or perpendicular to it. The anisotropic excited-state population density will relax or diffuse back into an isotropic distribution with an orientational relaxation time, at the same time as the regular population decay from the excited state takes place.

The excited state absorption of radiation whose polarization is parallel or perpendicular to the excitation pulse polarization should vary as follows:

\[
\alpha = \alpha_0 \{ \exp \left( -\gamma_{21} t \right) + \beta \exp \left[ -(\gamma_{21} + 1/\tau_{rot}) t \right] \}
\]

where \( \alpha_0 \) is the isotropic part of the initial absorption at time \( t = 0 \), \( \gamma_{21} \) is the population decay rate, \( \tau_{rot} \) is the rotational diffusion time, and \( \beta = 4/5 \) for parallel polarizations and \( \beta = -2/5 \) for perpendicular polarizations, assuming that the directions of the dipole moments of the transitions \( S_n \leftarrow S_1 \) and \( S_1 \leftarrow S_0 \) are parallel [14].

To study these rotational effects, we performed picosecond photoacoustic measurements like those described above on a solution of Rhodamine 6G in heavy water plus 2\% Ammonyx LO, using different polarizations of the 1064 nm probe pulse relative to the 532 nm excitation pulse. Heavy water was used because of its negligible absorption at 1064 nm in contrast with water and most of the organic solvents. To get a better signal to noise ratio, we also eliminated the single pulse selector and used the entire train of mode-locked pulses. A half wave plate was used
in the 532 nm beam to rotate its polarization and a polarizer in each beam selected the desired linear polarization.

The results are shown in Fig. 6, in which the delay-dependent part of the photoacoustic signal is plotted versus delay with the polarizations of the 532 nm and the 1064 nm beams either crossed or parallel. Because the entire mode-locked train was used, the signal is nonzero for negative delays, i.e., the n-th 1064 nm pulse still sees some excited states created by the (n - 1)-th 532 nm pulse that came about 5 ns before. For slightly positive delays, the striking difference in the signal amplitude for the two curves demonstrates the strong absorption anisotropy.

The initial slope of the decay curve at time $t = 0^+$ (just after an excitation pulse) for the population probed by a 1064 nm beam with its polarization parallel or perpendicular to the excitation beam polarization can be calculated to be

$$
\left( \frac{d\alpha}{dt} \right)_{t=0^+} = -\gamma_{21} \alpha_0 \left[ 1 + \frac{1}{\tau_{rot}} \right] (10)
$$

As expected, the decay rate for the parallel polarization case ($\beta = 4/5$) is much larger than for the perpendicular polarization case ($\beta = -2/5$). Our experimental results, although rather crude and noisy, fit very well with an expected population decay time of $4.1 \pm 0.2$ ns and a rotational decay time $\tau_{rot} = 2.5 \pm 0.5/\mu$s, both in agreement with published data [9,11,12]. As reported earlier [11,12], this rotational decay time is long compared to the rotational decay times for solutions in ethanol or methanol because the Rhodamine 6G molecule is bonded to a large micelle soap complex in water. Our measurements also confirm directly that the dipole moments of the transitions $S_n \leftrightarrow S_1$ and $S_1 \leftrightarrow S_0$ are parallel [14].

V. Conclusions

We believe that the combined picosecond pulse plus photoacoustic detection method demonstrated in this paper will become a useful and effective method for picosecond spectroscopy. This approach should be particularly applicable for measurements on weakly absorbing systems (such as dilute or expensive samples); for systems where excited-state fluorescence is not available as a detection mechanism; and for observations of weakly absorbing excited states in liquids.
or in solids. Much shorter laser pulses than used in our experiment are of course
now available, and can equally well be used to gain greater time resolution. The
use of more stable cw mode-locked lasers with greater pulse uniformity and higher
repetition rate would substantially improve the signal averaging in the experiments,
and further improvements in the cell design and electronics are also possible. The
use of a tunable mode-locked dye laser would permit the determination of complete
excited-state absorption spectra. As was pointed out in this study, difficulties do
arise when the probe beam wavelength is short enough for the ground state absorp-
tion to become important.

To our knowledge, this is the first time that rotational relaxation effects have
been observed on the excited-state absorption in organic dyes. These observations
give useful information about the relative dipole orientation for the two absorption
processes.

Note that most conventional methods of picosecond spectroscopy using pulse
and probe methods are susceptible to coherent artifacts, or induced grating effects,
when the “excite” and the “probe” pulses are coincident in time. These effects
should not exist when the photoacoustic detection is used because of its purely
thermal nature.

Appendix A. Analysis of Single-Wavelength Case

In some situations one may want to study the excited state absorption cross-
section of a sample at the same wavelength $\lambda_1$ as the one used for the excitation
from the ground state. Equations (1) through (4) will still be valid if we replace $I_2$
and $\omega_2$ by $I_1$ and $\omega_1$, respectively.

We first assume that the two light pulses are coincident in time ($\tau = 0$),
have a total intensity $I$ at the wavelength $\lambda$ for some duration $\tau_1$, and are turned
off thereafter. As before, the decay rate $\gamma_4$ is assumed to be very fast. The
photoacoustic signal will then be:

$$\text{PAS}(E, \tau = 0) = K N \frac{E}{E_{1S}} \frac{\gamma_{21} \gamma_1 + E/E_{1S}}{\gamma_{21} \gamma_1 + E/E_{1S}} \left\{ (\omega_{32} + \omega_{10}) \gamma_{21} \gamma_1 + \omega_{52} \frac{E}{E_{2S}} \right\}$$

$$+ \frac{1 - \exp\left(-\gamma_{21} \tau_1 - E/E_{1S}\right)}{\gamma_4 \gamma_1 + E/E_{1S}} \left\{ (\omega_{32} + \omega_{10}) \frac{E}{E_{1S}} - \omega_{52} \frac{E}{E_{2S}} \right\}$$

(A.1)
where \( F \) is the total energy fluence in the two pulses. This photoacoustic signal is plotted on Fig. 7 versus \( E/E_{1S} \) for different values of \( E_{1S}/E_{2S} = \sigma_2/\sigma_1 \) and \( \gamma_{21} \tau = 0.025 \). It is interesting to note that for the special case of \( \sigma_2/\sigma_1 = (\omega_{32} + \omega_{10})/\omega_{52} \), the photoacoustic signal simplifies to

\[
PAS(E, \tau = 0) = KN \frac{E}{E_{1S}} (\omega_{32} + \omega_{10})
\]

i.e., the photoacoustic signal is linear in \( E \).

Now when the two light pulses are separated by a large delay the second pulse will not see any excited molecules, since they will have decayed back to the ground level. Therefore the second light pulse will add up to the photoacoustic signal created by the first one in a completely independent fashion. Assuming both pulses have equal energy \( E/2 \), the photoacoustic signal will be:

\[
PAS(E, \tau \to \infty) = 2PAS(E/2, \tau = 0)
\]

Therefore there will not be any change in the photoacoustic signal when the delay between the two pulses is varied if \( PAS(E, \tau = 0) \) is a linear function of \( E \). The photoacoustic signal will only change with varying delay when \( PAS(E, \tau = 0) \) is a nonlinear function of \( E \).

A good measure of the photoacoustic changes when the delay is varied is the contrast coefficient defined as follows:

\[
R = \frac{|PAS(E, \tau = 0) - PAS(E, \tau \to \infty)|}{\text{Min}[PAS(E, \tau = 0), PAS(E, \tau \to \infty)]}
\]

where the denominator is the minimum of the two values \( PAS(E, \tau = 0) \) and \( PAS(E, \tau \to \infty) \). This quantity is fully equivalent to the ratio \( R \) we defined earlier (Eqs. (7) and (8)) and therefore will have the same notation.

This contrast ratio \( R \) is plotted in Fig. 8 versus \( E/E_{1S} \) for different values of \( \sigma_2/\sigma_1 \) and \( \gamma_{21} \tau = 0.025 \). As expected, the contrast has a maximum value of 1 only for a certain range of values for \( E/E_{1S} \) and only for \( \sigma_2/\sigma_1 \) sufficiently different from \( (\omega_{32} + \omega_{10})/\omega_{52} \). For \( \sigma_2/\sigma_1 = (\omega_{32} + \omega_{10})/\omega_{52} \), as expected from the linearity of Eq. (A.2), the contrast is null for all values of \( E/E_{1S} \).

ABSTRACT

The paper describes a new type of high resolution XUV radiation source which is based upon spontaneous anti-Stokes scattering of tunable incident laser radiation from atoms excited to metastable levels. The theory of the source is summarized and two sets of experiments using He (1s2s)1S atoms, produced in a cw hollow cathode and in a pulsed high power microwave discharge, are discussed. The radiation source is used to examine transitions originating from the 3p6 shell of potassium. The observed features include four previously unreported absorption lines and several sharp interferences of closely spaced autoionizing lines. A source linewidth of about 1.9 cm⁻¹ at 185,000 cm⁻¹ is demonstrated.

SPONTANEOUS RAMAN SCATTERING AS A HIGH RESOLUTION
XUV RADIATION SOURCE

I. INTRODUCTION

Recent interest in extreme ultraviolet (XUV) physics has created a demand for extremely high resolution spectroscopic tools in this spectral region. Studies of autoionization and Rydberg series in atoms, as well as in molecular spectra, have shown important structure on the scale of 1 cm\(^{-1}\) \[1\].

To reach this resolution at 500 \(\AA\), where 1 \(\AA\) is equivalent to 400 cm\(^{-1}\), requires an instrumental linewidth of 2.5 \(\AA\), or a resolving power of 200,000. A 10-meter monochromator with an aberration free, 6000 \(l/mm\) grating would attain this resolution at a slit width of 15 \(\mu m\). The lack of availability of such instruments, along with the difficulties of low throughput and order sorting has made an alternative approach desirable. In this paper we report the development of a new radiation source in the XUV \[2\] and its application to high resolution spectroscopy \[3,4\].

The radiation source is based upon spontaneous Raman scattering \[5,6\] of incident laser photons from excited metastable atoms. The metastable atoms may be produced in a discharge; in this work both cw hollow cathode and high power pulsed microwave discharges are used. Metastable atoms may also be produced with a pulsed hollow cathode discharge \[7\] or, as recently demonstrated \[8\], by photoionization of ground level atoms by soft x-rays from a laser produced plasma.
The upper and lower sidebands of the scattered radiation have frequencies equal to the sum and difference, respectively, of the metastable storage frequency and the frequency of the incident laser photon. By tuning the frequency of the incident laser, the frequency of the scattered radiation is tuned. Each sideband has a linewidth equal to the convolution of the incident laser linewidth and the Doppler width of the radiating atoms. The accessible spectral range is therefore determined by the range of available tunable lasers, and by the number of species which may be used for metastable storage.

The spontaneous Raman radiation is only generated while the pump laser is present. Hence, the source may operate in a short pulse mode, and even on a picosecond time scale. If the storage and terminal states of the Raman process have zero angular momentum, and the pump laser is polarized, then the spontaneous Raman radiation will also be polarized.

In the following sections of this paper we first discuss the theory of the spontaneous Raman scattering source. Attention is given to intensity and saturation effects which limit its brightness. We then describe experimental work which, although limited to helium as the storage species, demonstrates the source as narrowband (resolution greater than 100,000 at 550 Å) and broadly tunable (spectral range of about 7,500 cm\(^{-1}\)). The source is used to examine transitions originating from the \(3p^6\) shell of potassium. The observed features include four previously unreported narrow absorption lines and several sharp interferences of closely spaced autoionizing lines.

Finally, we consider the possibility of using the other inert gases, and also singly ionized column I metals for metastable storage. These species may allow a coverage of about 75% of the spectral region from 500 Å to 1500 Å.
A. LINEAR SCATTERING CROSS SECTION

Figure 1 shows a partial energy level diagram of He. Energy is assumed to be stored in the He 1s2s 1S metastable level at 20.6 eV. The initial level \( |i\rangle \), is connected to the ground He 1s 2 1S level \( |f\rangle \) through a sum of intermediate levels \( |n\rangle \) which have dipole allowed transitions to both the initial and final levels.

If a monochromatic pump field at frequency \( \omega_p \) is applied to the system, the spontaneous Raman scattering of photons from metastable atoms can be visualized as a transfer of population to virtual levels at energies \( \hbar (\omega_{if} \pm \omega_p) \) followed by spontaneous decay of this virtual population to the ground level \( |f\rangle \). The process may be considered from either the point of view of an induced Einstein A coefficient, or of a linear scattering cross section. If \( N \) is the density (atoms/cm\(^3\)) of metastable storage atoms, then the number of XUV photons per sec which are scattered from a cm\(^3\) of volume is

\[
XUV_{\text{photons/sec}} = N \Delta \sigma_{\text{induced}} = \frac{N \sigma_{\text{spont}}(P/A)_{\text{pump}}}{\hbar \omega_p}
\]

(1)

For laser pump intensities which are sufficiently low that saturation effects are not present, the differential scattering cross section for the upper sideband is given by
Fig. 1--Atomic energy level diagram of $^4\text{He}$.
\[ \frac{\text{d} \sigma_{\text{spont}}}{\text{d} \Omega} = \frac{1}{4\pi \hbar^2} \frac{\omega_s^3 \omega_p}{\epsilon^2 \epsilon_0} \sum_n \frac{\langle f|\vec{q} \cdot \vec{e}_n^*|n\rangle \langle n|\vec{q} \cdot \vec{e}_p^*|i\rangle}{E_n - E_f + i\omega_s} \]

\[ + \frac{\langle f|\vec{q} \cdot \vec{e}_p^*|n\rangle \langle n|\vec{q} \cdot \vec{e}_s^*|i\rangle}{E_n - E_f - i\omega_s} \]

where \( \omega_s \) is the frequency of the scattered radiation \((\hbar \omega_s = E_f - E_i \pm \omega_p)\), \( \omega_p \) is the frequency of the pump photon, \( \vec{e}_s \) and \( \vec{e}_p \) are the respective polarization unit vectors, \( \vec{q} = -e \mathbf{r} \mathbf{1}_1 \) is the dipole moment operator for the atom, and \( E_i, E_n, \) and \( E_f \) are the energies of the initial, intermediate, and final states. The sum over intermediate states is performed over all dipole allowed transitions including the continuas. To obtain the cross section for the lower sideband, simply replace \( \vec{e}_p \) by \( \vec{e}_p^* \) in Eq. (2).

In the case of He, the upper sideband will have smaller resonance denominators, and therefore a significantly larger scattering cross section than does the lower sideband.

Figure 2 shows the upper sideband (anti-Stokes) scattering cross section \((\%)\) for He where the initial state is the metastable singlet level \( \text{He} 1s2s \, 1S \), the final state is the ground level, and the intermediate levels are \( |n\rangle = 1snp \, 1P \) and the \( 1s\epsilon p \, 1P \) continuum. The resonances are due to the intermediate levels \( 1s2p \, 1P \) at 584 Å and \( 1s3p \, 1P \) at 537 Å. As a result of both the \( \omega_s^3 \) dependence of the scattering, and also of the relatively close approach to resonance, the per atom anti-Stokes scattering cross section in the XUV is often about six orders of magnitude larger than is typically encountered in the visible region of the spectrum.
Fig. 2--Plot of anti-Stokes scattering cross section vs. tunable laser wavelength and scattered XUV frequency.
B. \textbf{SATURATION}

Three types of saturation of the anti-Stokes radiation source are typically encountered. These are: (1) simple depletion of the stored metastable population, (2) microscopic (per atom) saturation of the scattering process, and (3) macroscopic saturation, in the Planck equilibrium sense, of the emitting media.

1. \textbf{Depletion}

If we assume, as almost always will be the case, that the stored metastable population is not so large that the Raman scattering process represents a significant loss to the incident laser beam, then the laser pulse energy fluence which in essence scatters or depletes all of the stored population is

\[ (J/A)_{\text{saturation}} = \frac{\hbar \omega_p}{\sigma_s} \]

For a typical scattering cross section in He of \( \sigma_s = 5 \times 10^{-23} \text{ cm}^2 \), and \( \omega_p \) corresponding to 6000 Å, this occurs at \( J/A = 6.6 \times 10^3 \text{ joules/cm}^2 \). For beam size of several \( \text{mm}^2 \), as will most often be used in the spectroscopic applications of this source, this type of saturation is unlikely to be encountered.

2. \textbf{Microscopic Saturation}

As the incident laser power is raised, or a particular intermediate resonance is approached, all of the atoms in the storage level are in effect transferred to the virtual level and may then not radiate or scatter at a rate faster than the Einstein A coefficient of the approached intermediate
level. As this large field, or near resonance region, is approached, frequency shifts of the storage level and therefore of the scattered Raman radiation also occur, and may limit the resolution of the radiation source.

A simple and nearly exact solution of the near resonant problem is obtained from the dressed atom approach [10]. Defining the quantity $\theta$ by

$$\theta = \tan^{-1} \left( \frac{\mu_{in} E_p}{\hbar \Delta \omega} \right)$$

(4)

where $\mu_{in}$ and $\Delta \omega$ are the matrix element and detuning from the near resonant level [$\Delta \omega = \omega_n - (\omega_i + \omega_p)$]; the induced emission rate is

$$A_{\text{induced}} = \left( \frac{\omega_s}{\omega_n^f} \right)^3 \sin^2 \frac{\theta}{2} - A_n^f$$

(5)

and the frequency of the scattered anti-Stokes radiation is

$$\omega_s = (\omega_i - \omega_f) + \omega_p - \frac{\delta}{2}$$

(6a)

where

$$\delta = \Delta \omega \left( \frac{1 - \cos \theta}{\cos \theta} \right)$$

(6b)

When $\theta$ is small (low pump fields or large detunings), Eq. (5) reduces to a single term of Eq. (2).

3. Macroscopic Saturation

In a typical discharge or plasma the population of the final level (in He, the ground level) of the Raman process is often several orders of magnitude greater than the population of the metastable storage level. Incident
laser photons not only cause emission of XUV photons from the storage level, but also cause two-photon absorption of these same photons by atoms which are in the ground level. The interplay of the two-photon emission, i.e., the Raman emission, and the two-photon absorption yield a source brightness which is the same as that of a one-photon blackbody, except that the usual one-photon absorption coefficient is replaced by the two-photon absorption coefficient \[2\].

The brightness \( B(\omega) \) (power per bandwidth in radians/sec per solid angle and area) for a sample of thickness \( L \), is given by

\[
B(\omega) = \frac{\hbar \omega^3}{8\pi^3 c^2} \left[ \frac{1}{(N_f/N_i) - 1} \right] \left[ 1 - e^{-(N_f - N_i)\sigma(2)(\omega)L} \right] \tag{7a}
\]

\[
\sigma(2)(\omega) = \frac{c^3 \sigma_{\text{spont}}}{\omega^2} \frac{d\sigma}{d\theta} \frac{(P/A)_{\text{pump}}}{\hbar \omega} g(\omega) \tag{7b}
\]

where \( \sigma(2) \) is the two-photon absorption cross section for XUV radiation which results from the presence of the laser field \( \omega_p \). The lineshape \( g(\omega) \) is the convolution of the initial (metastable) and final level lineshapes.

At frequencies or cell lengths where the column is two-photon opaque, the brightness of the spontaneous Raman radiation source is that of a blackbody at a Boltzmann temperature of the metastable level, i.e., \( N_i/N_f = \exp \left[ - (\hbar \omega_{1f}/kT) \right] \). In the optically thin region where \( N_f\sigma(2)L \ll 1 \), the brightness reduces to that obtained from the linear scattering cross section of Eq. (2).
III. EXPERIMENTAL RESULTS

A series of experiments was performed to demonstrate the use of spontaneous Raman scattering as a tunable high resolution source for absorption spectroscopy. The metastable helium $1s^2 2s^1 S$ level was used as the Raman medium, producing radiation in the $500 \AA$ spectral region (anti-Stokes upper sideband scattering). We used this source to examine potassium absorption features due to autoionizing transitions originating from the $3p^6$ shell. Two methods were used to excite helium atoms to the $1s^2 2s^1 S$ storage level: a cw hollow cathode discharge and a high power pulsed microwave discharge. The first technique produced anti-Stokes radiation which was brighter than all other XUV emission from the plasma, thus simplifying detection; however, the radiation was relatively weak, thus limiting the tuning range. The second technique produced much larger anti-Stokes signals and greater tuning ranges, but the increased level of background XUV plasma emission made the use of additional filtering necessary. Both methods are described below.

A. LOW CURRENT HOLLOW CATHODE DISCHARGE

A schematic of the basic apparatus is shown in Fig. 3. Helium metastable $1s^2 2s^1 S$ population was produced in a 60 cm long hollow cathode discharge and a tunable dye laser (Nd:YAG pumped Quanta-Ray PDL-1) was directed down the discharge by a right-angle turning prism. Backward scattered anti-Stokes radiation passed by the prism (which obscured about one-half the aperture), through a potassium vapor cell, through an aluminum filter, and was incident on an electron multiplier tube.

The discharge consisted of a stainless steel cylindrical cathode 1.2 cm in diameter inside a concentric 2.5 cm stainless steel tube which served as
Fig. 3--Schematic of hollow cathode apparatus used for absorption spectroscopy of potassium.
the anode. The cathode had a slot 0.6 cm wide along the 60 cm active length of the discharge which allowed the glow to reside inside the cathode. Typical operating parameters of the discharge were 2 torr helium, 190 V, and 30 ma, which, based on previous measurements [11], implies a population of 1s2s 1S metastables of about $10^{11}$ atoms/cm$^3$. The current through the discharge was kept low because it was found that the metastable population did not increase appreciably with current (up to a few hundred ma), but the background radiation from the plasma (predominantly resonance line radiation at 584Å and 537Å) increased linearly with the applied current. Thus, the largest signal-to-noise ratio was obtained at the lowest stable operating current of the discharge.

The potassium vapor cell consisted of a stainless steel tube 1.2 cm in diameter with a stainless steel wick. The active hot zone was 5 cm long and typically was operated at a potassium vapor density of $10^{15}$ atoms/cm$^3$ (260°C). The ambient helium discharge pressure slowed the diffusion of potassium both into the discharge and to the aluminum filter which served to separate the 2 torr helium pressure from the $10^{-6}$ torr operating pressure of the electron multiplier. Experiments were performed with potassium having a minimum purity of 98% and 99.95% with the same results.

The XUV photons transmitted through the potassium cell impinged directly upon the first dynode of an EMI D233 electron multiplier, liberating photoelectrons which were subsequently amplified in the remaining 13 stages of the tube. This fast linear focused tube provided single output pulse widths of $\sim 5$ ns and a gain of $\sim 10^6$ at an applied voltage of 3.7 kV. The output of the electron multiplier was processed with a fast preamplifier and a 10 ns wide gated integrator. A small computer digitized and recorded the resultant
voltage along with the input dye laser intensity. The computer also tuned the laser in steps of 0.04 Å.

For incident laser pulses of 50 mJ at 4000 Å we calculate that about $4.5 \times 10^7$ XUV photons per laser pulse are produced in the 60 cm long discharge at the anti-Stokes wavelength, 6066 Å. The solid angle of the detector reduces the flux to 200 photons/pulse or (for the 10 pulse per second repetition rate) 2000 photons/sec. Thus, the ratio of the number of incident laser photons to the number of effective XUV photons is expected to be greater than $10^{14}$. It is therefore essential to provide large discrimination against the visible laser photons. This was accomplished (1) by using a geometry which utilized backscattered XUV radiation, (2) by the $\sim 5 \times 10^{-8}$ rejection of the visible light by the aluminum filter, and (3) by the high work function of the electron multiplier. Even with these factors, if the incident laser reflected off an edge near the end of the discharge, the reflection overwhelmed the detected XUV photons. The transmittance of the aluminum filter (Luxel TF-10la, a 1500 Å thick film of Al alloyed with 1% silicon supported by a nickel mesh) is useful from $\sim 850$ Å to $\sim 150$ Å. At 550 Å approximately 10% of the incident flux is transmitted, whereas in the visible the filter is specified at less than $5 \times 10^{-8}$ transmittance [12]. Therefore, we estimate the incident flux onto the detector at 200 photons/sec; assuming a detector quantum efficiency of 10% [12], we obtain a count rate of 20 counts/sec, which agrees well with our observations.

The spectral regions studied with this apparatus are shown in Table 1. Typical absorption scans are shown in Fig. 4. These scans are computer generated plots in which each point represents the sum of integrated signals from 5 laser settings, a total of 50 pulses covering $\sim 0.75$ cm$^{-1}$. The XUV

Fig. 4—Absorption scans of potassium obtained with hollow cathode apparatus. Potassium vapor density is \(10^{15}\) atoms/cm\(^3\), and cell length is 5.0 cm.
signal was normalized to the relative dye laser intensity, which has the effect of increasing the statistical fluctuation in regions of lower laser intensity.

The XUV frequency at each data point was obtained by adding the laser frequency to the frequency of the storage level, $^4\text{He}\, 1s2s\, ^1S$, which has been accurately measured to be $166,277.55 \pm 0.15 \text{ cm}^{-1}$ [14,15]. The laser frequency was determined from the dial of the Quanta-Ray dye laser; this dial reading was calibrated using known Ne and Kr lines, and found to be resettable to $\pm 1 \text{ cm}^{-1}$.

Table 2 summarizes the energies and linewidths of the observed potassium absorption features. The broader features were observed by Mansfield [16], Mansfield and Ottley [17], and Kavei, et al. [18]. The narrower features have not been reported previously. We estimate that Mansfield [16] had an instrumental linewidth of approximately $40 \text{ cm}^{-1}$ based upon microdensitometer traces he supplied. Thus, it is not surprising that weak lines a few cm$^{-1}$ in width would escape detection. (Assuming that the linewidths of these features are about equal to that of the anti-Stokes radiation, a 50% absorption in Fig. 4 corresponds to an oscillator strength of $f = 3 \times 10^{-4}$.)

Our measured absorption linewidths were a function of the potassium vapor pressure, and the widths reported in Table 2 are the minimum full widths at half maximum obtained by reducing the cell pressure to a value at which negligible change in width was seen with further reduction. The narrowest observed absorption feature (at 185,806 cm$^{-1}$) had a measured width of $1.9 \text{ cm}^{-1}$, which approaches the theoretical linewidth of the anti-Stokes radiation, i.e., the convolution of the 0.3 cm$^{-1}$ laser linewidth and the room temperature Doppler width of $\approx 1.3 \text{ cm}^{-1}$ of the emitting helium atoms [19].

(a) M. W. D. Mansfield (1975) [Ref. 16].
(b) G. Kavei, et al. (1977) [Ref. 18].
Note that potassium vapor (at 260° C) has a Doppler width of \( \sim 0.5 \text{ cm}^{-1} \) in this spectral region. A calculation which convolves the various linewidths involved shows that an observed \( 1.9 \text{ cm}^{-1} \) linewidth implies a natural width of the line of \( \sim 0.5 \text{ cm}^{-1} \). This corresponds to an autoionizing time of \( \sim 10 \text{ ps} \), which is consistent with calculated autoionizing times for levels in potassium which are not allowed to autoionize to first order (in LS coupling) [20]. Thus, the narrow absorption lines are probably the result of transitions from the \( 3p^64s \) ground level to levels that, in the approximation of LS coupling, are forbidden by selection rules to autoionize, such as odd parity doublet series levels with even orbital angular momentum and levels in the quartet series.

As a result of the operation of the discharge at very low current, this apparatus had the inherent disadvantage of producing low signal levels. For a total of 50 pulses integrated per data point, we found that a dye laser energy of \( \sim 12 \text{ mJ/pulse} \) was necessary to achieve an acceptable 3 to 1 signal-to-noise ratio. The spectral range that could be scanned in a reasonable time period (the scans shown in Fig. 4 took \( \sim 1-1/2 \text{ hours} \) each to complete) was therefore limited to wavelengths generated using tunable radiation from the high output laser dyes. Thus, in order to investigate other spectral regions the inherent anti-Stokes signal level must be increased.

B. PULSED HIGH POWER MICROWAVE DISCHARGE

We made two changes to increase the brightness and thus the tuning range of the anti-Stokes radiation source: a high power microwave discharge was used to produce a larger population in the He \( 1s2s \, ^1S \) storage level, and the effective solid angle for collection of anti-Stokes radiation was improved.
The basic geometry is similar to that used previously and is shown in Fig. 5. Microwave pulses at 9.375 GHz, 2 μs long, with a peak power of about 500 kW were generated by a Varian SFD-303 coaxial magnetron and coupled into a 90 cm long, 4 mm i.d. quartz tube located inside a section of x-band waveguide, centered adjacent to the narrow wall. Helium gas at ~ 5 torr was flowed slowly through the tube. The helium broke down regularly during the rising edge of the microwave pulse; approximately 60% of the incident microwave energy was absorbed and less than 5% was reflected. Previous measurements [21] of microwave excited helium plasmas indicate that 1s2s 1S storage level densities of about $10^{13}$ atoms/cm$^3$ are typically obtained, or about 100 times larger than achieved with the hollow cathode.

In addition, this apparatus collected a much larger fraction of the generated anti-Stokes radiation by making use of near-grazing incidence reflections of the XUV radiation at the inside surface of the quartz tube. At 500 Å, quartz reflects 90% of radiation incident at 88° [22], and the tube acts like a waveguide for these grazing rays. As illustrated in Table 3, the effective solid angle collection of such a tube can be larger by a factor of $10^2 - 10^3$ than a similar geometry where there is no reflection of grazing rays. The second column of Table 3 shows the solid angle collected from a uniformly emitting source through a quartz tube of inside diameter 4 mm assuming no wall reflections, i.e., as if the tube were replaced by apertures at its ends. The third column shows the solid angle collected for the same geometry, except that the reflections are included. We note, however, that these reflections depolarize the initially polarized anti-Stokes radiation.

</table>
The potassium vapor cell (Fig. 6) was redesigned so as to maintain the grazing reflection geometry. An alkali resistant glass tube was slotted (1 mm wide) to allow potassium vapor to permeate throughout, and a heater was wound on the glass tube to keep it hotter than the wet stainless steel wick, so as to prevent potassium condensation inside the tube. The potassium cell had an active hot zone 4.5 cm long. Over approximately 30 hours of operation, the potassium cell's throughput of XUV radiation decreased by a factor of 5. Apparently, this was due to contamination of and/or reactions on the inside surface of the glass tube, and a subsequent loss of reflectivity, since the throughput returned to its original value when the contaminated tube was replaced.

The main disadvantage in using the more intense microwave discharge was that the intensity of the spurious XUV radiation was much larger than the anti-Stokes signal intensity. The $\int_{\lambda} \lambda^4 I_\lambda d\lambda$ integrated resonance line intensity was measured to be 15 times greater than the anti-Stokes intensity (using 50 mJ of laser energy at 6000 Å). As a result, it was necessary to filter the resonance radiation from the anti-Stokes radiation. A McPherson 225 one-meter normal incidence vacuum monochromator with a 1200 l/mm grating ruled over a 30 mm x 50 mm area and coated with platinum was used in first order as a filter against the resonance radiation. The linear dispersion was 8.3 Å/mm, and the monochromator slit widths were set to discriminate against the nearest noise feature, while passing the desired range of anti-Stokes radiation. For the spectral range that we examined, the nearest noise feature was the second resonance line at 537.0 Å. Typically, the slits were set at a width of 0.8 - 1.0 mm, and thus, the resolution of the apparatus was due entirely to the spectral width of the anti-Stokes radiation.
The spectrometer, however, introduced a large throughput loss into the system. For an incident pulse energy of 25 mJ at 6000 Å through the helium plasma, we calculate that approximately $3.2 \times 10^9$ anti-Stokes photons are generated. Of these photons scattered into all directions, only an estimated 0.029%, or $9.3 \times 10^5$ photons emerge from the end of the potassium absorption cell. (Without the grazing-reflection collection this output would have been smaller by roughly 200.) Furthermore, the solid angle of the spectrometer reduces the collected flux by an additional factor of 15, the grating has an efficiency in the XUV of about 4%, and the aluminum filter transmits 10% of the anti-Stokes radiation. Thus, we estimate that about 250 photons strike the detector for each laser pulse. At ten laser pulses per second, this implies a flux of $2.5 \times 10^3$ photons/sec striking the detector, or for a 10% detector quantum efficiency, a net count rate of 250 per second. The observed count rate was $\sim 200$/sec, 10 times greater than with the hollow cathode.

The temporal behavior of the microwave excited discharge is shown in Fig. 7. The anti-Stokes radiation and resonance fluorescence intensities are proportional to their respective excited state populations. Thus, we conclude that in the first few hundred ns after breakdown (the avalanche period), the excited state populations reached their maximum value. For the duration of the microwave pulse, resonance fluorescence remained large, but the anti-Stokes radiation decreased to a small level. After the microwave pulse, recombination occurred in the cooling plasma, and both anti-Stokes radiation and resonance fluorescence regained intensity. The anti-Stokes radiation decayed during recombination with a time constant of $\sim 4$ µs, whereas resonance fluorescence decayed with a shorter time constant of
~ 2 µs. Thus, the ratio of anti-Stokes intensity to resonance line intensity was largest in this recombination tail.

Unfortunately, operation late in the recombination period has a serious disadvantage. The measured widths of absorption features in potassium were about 2.5 cm⁻¹ wider than measurements of the same features made during the avalanche period. We believe that this is due to an increase in the temperature of the metastables and hence, a larger Doppler width during the recombination period. The most likely mechanism for this heating is the elastic collisions of neutrals and ions with hot electrons, and the subsequent formation of hot metastables during the recombination period. From linewidth measurements during the recombination period we estimate that the Doppler width is 3.5 cm⁻¹, which implies an atomic kinetic temperature of ~ 3000 K (0.26 eV). The spectral width of the anti-Stokes radiation during the avalanche period was confirmed to be equal to that obtained with the hollow cathode discharge by measuring the linewidths of the same potassium absorption features. Because of this effect, all the measurements and spectra reported were made during the avalanche period.

Using the microwave discharge we extended the spectral region examined in potassium to 536.8 Ǻ - 558.4 Ǻ, as shown in Table 4. To achieve a signal-to-noise ratio of 3 to 1 with an integration of 50 laser pulses per point, a minimum of ~ 1 mJ of laser energy per pulse was required. Commercial sources of such energy per pulse are available to at least 2 µm, which implies a possible XUV spectral range of ~ 537 Ǻ - 584 Ǻ.

Table 5 lists a number of additional potassium absorption features we observed using the microwave excited discharge; all have been previously observed by Mansfield [16]. Typical absorption scans are shown in Fig. 8, which are computer generated plots containing 1024 points corresponding to laser

wavelength settings separated by 0.18 Å. To reduce the effects of background
drifts, the computer rapidly scanned the laser wavelength and recorded the
collected XUV flux level at each laser wavelength setting. At the end of
each scan the laser was blocked to determine the background level. The
plots of Fig. 8 represent the sum of 50 such scans, each one having only
one laser pulse at each laser wavelength setting. The 50 scans took about
1-1/2 hours to complete.

Figure 8(a) shows two fairly narrow features at 181745 cm\(^{-1}\) and 181519
\(\text{cm}^{-1}\), while Fig. 8(b) shows two broad, asymmetric features centered
\(180794 \text{ cm}^{-1}\) and \(18084.0 \text{ cm}^{-1}\) separated by a narrow \(\sim 100\%\) transmissi\(\text{on}\) window.
(The transmission level at the right end of the scan is reduced by an additional feature at 180547 cm\(^{-1}\), beyond the range of the displayed scan.) The
two (somewhat saturated) absorption features in Fig. 8(b) have very asymmetric
profiles due to a strong interference between two discrete levels lying nearby
in a single continuum. A complete cancellation of absorption cross section
between two levels can be explained in terms of a Beutler-Fano [23] profile,
and a simple analysis yields the ratio of the absorption cross section to
the underlying continuum cross section. The values of the linewidths given
in Table 5 for these levels were obtained by fitting absorption data taken
at lower density, shown in Fig. 9, to the theoretical results. The theoretical
calculation is represented by the solid line.

Highly asymmetric features such as these are somewhat rare in this re-
gion of the potassium absorption spectrum because of the small background
photoionization cross section [24]. The Fano lineshape parameter \(q\) for a
single discrete state in a continuum is then very large (typically 30 - 50 in
potassium), and hence, the lineshape function is quite symmetric. In the
Fig. 9—Fit of theoretical Fano profile to potassium absorption data.
case discussed above, with two discrete states lying nearby, one can visualize the autoionization wing of one state as increasing the "background" photoionization cross section the other state sees. The $q$ parameter of this state is thereby reduced, resulting in a very asymmetric lineshape. This intuitive approach is confirmed by the more exact result shown in Fig. 9.
IV. EXTENSION TO OTHER SYSTEMS

Using helium as the storage medium, the coverage of the spontaneous Raman anti-Stokes radiation source is limited by practical tunable lasers to the spectral region from approximately 537 Å to 584 Å. To access other spectral regions one must use different storage levels or other species.

Table 6 and Fig. 10 show how the other inert gases might be used to allow coverage of new spectral regions. In all of the inert gases, except for helium, the state of primary metastability has a total angular momentum of $J = 2$ and is also of opposite parity to that of the ground level [25]. In order to use these lowest metastable levels for anti-Stokes scattering one must therefore use a low power fixed frequency laser to resonantly transfer the population to a level of the same parity as ground and then use an intense tunable laser to generate the lower spontaneous Raman sideband. The $J = 1$ intermediate level will resonantly enhance the scattering cross section for this lower sideband.

Table 6 notes the primary storage level in each of the inert gases, the wavelength of the weak transfer laser, the center wavelength of the strong tunable laser, and the center wavelength of the emitted XUV radiation. The final column of this table notes the Doppler width for each of the species at 300°K.

Table 7 shows how the alkali ions might be used in an iso-electronic analogy to the noble atoms in Table 6. The Na II system which is iso-electronic to neon is shown in Fig. 11. We note that spontaneous anti-Stokes scattering in Li II has been observed by Willison, et al. [26].

One difference in using the iso-electronic column I ion is that the primary storage level may be populated by creating a core shell hole by

photoionization. In recent experiments, Caro, et al. [8] have used photoionization to produce populations as large as $3 \times 10^{15}$ ions/cm$^3$ in the helium-like Li$^+$ triplet metastables.

If we assume that a frequency interval of 10,000 cm$^{-1}$ can be attained with each of the Raman systems listed in Tables 6 and 7, then the total spectral range accessible to the anti-Stokes radiation source would be that shown in Fig. 12. This represents approximately 25% of the frequency interval from 200 Å to 1500 Å and approximately 75% of the interval from 500 Å to 1500 Å.
Fig. 12--Possible spectral regions which could be examined using the spontaneous Raman source.
V. CONCLUSION

The experiments described in this paper have shown that the spontaneous Raman anti-Stokes radiation source may be used to obtain very high resolution over limited spectral regions. The complexity of changing the storage species will limit the source to situations where features have been previously identified with lower resolution apparatus. Very often it is the case that the center wavelength which is obtainable from an ionic species, for example, 601 Å from K II (Table 7), coincides with the region of most interest for studying the core-excited spectrum of the neutral species. For example, if one is able to obtain ± 15,000 cm⁻¹ of tuning centered at 601 Å, this would cover the spectral region from 551 Å to 660 Å. This would allow examination of a good portion of the interesting spectral region of K I.

Other properties of the spontaneous Raman anti-Stokes radiation source which may be useful are its controlled polarization and the ability to produce pulses as short as that of the incident laser.

The ultimate usefulness of this source will depend on the development of convenient methods for producing large metastable populations. Two promising approaches are the pulsed hollow cathode technology demonstrated by Falcone, et al. [7] and metastable production by photoionization with laser produced soft x-rays [8].
