Fundamental Research Data Base ...................................... 225
INTRODUCTION
by
L. F. Guseman, Jr.

The organizational meeting for the NASA Fundamental Research Program in "Mathematical Pattern Recognition and Image Analysis" (MPRIA) was held at the NASA/Johnson Space Center in August, 1982. At this meeting each of the fifteen principal investigators briefly outlined the goals of their particular proposed research efforts. Most of the efforts (those outside NASA) had just been funded (July 16, 1982), and investigations were just getting underway.

In order to gain a better understanding of and stimulate discussions between the individual research efforts, it was decided to conduct two technical workshops at Texas A&M University about six months into the program. The first workshop was held January 27-28, 1983 and consisted of investigators from the "Mathematics/Statistics" areas. The second workshop was held February 3-4, 1983 and consisted of investigators from the "Pattern Recognition" areas.

Each of the workshops was conducted in an informal manner. Most of the time was spent in lively technical discussions about each of the research efforts. Additional time was spent discussing the availability of data sets. Dr. R. P. Heydorn announced the availability of a data tape that has been compiled for use by the research teams. Details concerning the content and format of the tape are discussed in the document entitled "Fundamental Research Data Base" appearing in the Appendix of these proceedings.

Agendas and lists of participants for the workshops appear in their respective Proceedings.

TEXTURAL EDGE DETECTION AND SENSITIVITY ANALYSIS

by

K. Sam Shanmugan
Department of Electrical Engineering and
Remote Sensing Laboratory
University of Kansas
Lawrence, Kansas 66045
TEXTURAL EDGE DETECTION:

- Develop an optimum (global) textural edge detection operator based on statistical models for texture.

SENSITIVITY ANALYSIS:

- Analyze the effects of the imaging process on the textural patterns of a scene as it appears in the image -- i.e., separate scene-induced textural patterns from sensor-induced textural patterns.
TEXTURAL EDGE DETECTION

• Texture < Primitive Elements

• Structural Arrangement

X(t)

• Textural Edge Detection Operators:
  • Local Operators
  • Global Operators
  • Optimum

• Let $X(t) = X_1(t) \left[1 - u(t-t_0)\right] + X_2(t)u(t-t_0) + n(t)$

Want to process $X(t)$ using a LTV operator and produce $Y(t)$ that best approximates $\delta(t-t_0)$. $X_1(t)$ and $X_2(t)$ represent random process models for two textural classes that form a boundary at $t = t_0$. 
OPTIMUM TONAL EDGE DETECTION OPERATOR:

\[ X(t) \]

Find \( h(t) \) such that

\[
\alpha = \frac{\int_{-1/2}^{1/2} y^2(t) \, dt}{\int_{-\infty}^{\infty} y^2(t) \, dt}
\]

is maximized, subjected to the constraints

(1) \(|H(f)| = 0 \text{ for } |f| > B\)

(2) \( h(t) \) is LTIV
OPTIMUM TONAL EDGE DETECTION OPERATOR

- **Soln:**
  
  $$y(t) = a_1 \psi_1(c, t), c = B^{1/2}$$
  
  $$H(\omega) = \frac{y(\omega)}{X(\omega)}$$
  
  $$\approx \omega^2 e^{-c\omega^2}, |\omega| < B$$

  (edge model used: unit step and exponential)

- An approach similar to the one described above can be used to derive an optimum textural edge detection operator.

- In order to derive an optimum textural edge detection operator we need:
  
  - random field models for texture
  - edge models
  - performance measure
  - frequency domain models for textural fields
  - $$H(\omega) = \frac{y(\omega)}{F(G_x(f); G_y(f))}$$
**FREQUENCY DOMAIN DESCRIPTION OF**

**MARKOV TEXTURAL FIELD MODELS**

\[ X(t) = \sum_{i=1}^{\infty} A_i \ p_{m_i} (t-t_i) \]

\( \{A_i\} = \text{Amplitude sequence} \)

\( p_1, p_2, \ldots, p_N : N \text{ primitive elements} \)

\( \{m_i\} : m_i \in [1, 2, \ldots, N] \text{ indicates which one of the } N \text{ primitives is present at the } i\text{-th location} \)

\( \{t_i\} : \text{Location of the } i\text{-th primitive} \)

---

*Want to find \( G_X(f) \)
TEXTURAL FIELD MODELS

ASSUMPTIONS:

1. a. \( \{ t_i \} \) - uniformly distributed locations

1. b. \( \{ t_i \} \) - Poisson sequence with an exponential
distribution for inter-location distance

2. a. \( \{ A_i \} \) : Constant

2. b. \( \{ A_i \} \) : Correlated sequence

3. a. \( p_1, p_2, \ldots, p_N \) : deterministic shapes

3. b. \( p_1, p_2, \ldots, p_N \) : random processes

4. a. \( \{ m_i \} \) : Independence sequence

\( \{ m_i \} \) : Homogeneous markov sequence
COMPLETED MODEL:

\[ \{ t_i \} : \text{uniformly distributed} \]

\[ \{ A_i \} : \text{constant} \]

\( p_1, p_2, \ldots, p_N : \text{deterministic} \)

\[ \{ m_i \} : \text{markov} \]

\[ P \left( \text{occurrence of } p_k \right) = \pi_k \]

\[ P \left( \text{occurrence of } p_i \text{ followed by } p_j \text{ after } n \text{ locations} \right) = p_{ij} \]

\[ X(t) = \sum_{-\infty}^{\infty} p_{m_i} (t-mT_s) \]

\( T_s = \text{average spacing between elements} \)
POWER SPECTRAL DENSITY:

\[
G_x(f) = \frac{1}{T_s^2} \sum_{n=-\infty}^{\infty} \left| \sum_{j=1}^{N} \pi_j S_j\left(\frac{n}{T_s}\right) \right|^2 \delta \left(f - \frac{n}{T_s}\right) \\
+ \frac{1}{T_s} \sum_{j=1}^{N} \pi_j \left| S_j'(f) \right|^2 \\
+ \frac{2}{T_s} \text{Re} \left\{ \sum_{j=1}^{N} \sum_{k=1}^{N} \pi_j S_j'^*(f) S_k'(f) Q_{jk}(f) \right\}
\]

where:

\[
S_k(f) = F \left\{ p_k(t) \right\}
\]

\[
S_k'(f) = F \left\{ p_k(t) - \sum_{j=1}^{M} \pi_j p_j(t) \right\}
\]

\[
Q_{jk}(f) = \sum_{n=1}^{\infty} p_{jk}(n) \exp \left( -i 2 \pi n f T_s \right)
\]
SPECIAL CASE:  

N = 2 ; \{m_i\} - Independence sequence; equal probability

\[ G_x(f) = \frac{1}{T_s^2} \sum_{n=-\infty}^{\infty} \left| p S_1 \left( \frac{n}{T_s} \right) + q S_2 \left( \frac{n}{T_s} \right) \right|^2 \delta \left( f - \frac{n}{T_s} \right) + \frac{1}{T_s} p(1-p) \left| S_1'(f) - S_2'(f) \right|^2 \]
RESEARCH PLAN:

- Generalize (2-dimensional, \( t = (x, y) \); Poisson)

- Find \( F(G_{x_1}(f), G_{x_2}(f)) \)

  (Edge model)

- Test filters on simulated fields

- Develop estimation procedures, test on actual image data
TEXTURAL EDGE DETECTION

**Approach:**

- Define appropriate measures of performance - What is "optimum"?

- Develop random field models for different classes of textures (different means, covariance/co-occurrence matrices)

- Given $X_1(t)$ and $X_2(t)$ derive the transfer function of the optimum filter subjected to appropriate constraints

- Modify the transfer function to take into account the presence of noise in the input image

- Find a sub-optimum filter for a wide class of textural edges

- Test the filter on natural and synthesized textural edges
SENSITIVITY OF TEXTURAL FEATURES

- Textural Patterns in an image
  - scene or target induced
  - sensor induced (due to sensor transfer function, geometry, nature of the illumination, etc.)

- In a LANDSAT-type image, the textural patterns that appear in the image usually represent the textural patterns of the underlying scene (assuming that the illumination variations and shadows are minimum).

- In a SAR image of a scene with significant terrain relief, the textural patterns that appear in the image may be very different than the textural patterns in the underlying scene due to layover, shadowing, fading, etc.

- Objective of the proposed research effort is to develop mathematical models and methodologies for evaluating the effects of the imaging process on the textural patterns of a scene as it appears on the image.

SENSITIVITY ANALYSIS

Research Plan:

• Develop random process models of terrain elevation, and backscatter variations of typical scene categories (agricultural, forestry, urban areas, hilly and mountainous terrains, water bodies, etc.). The models will be in a parametric form, and the scene texture will be described by the parameter values and the model type.

• Develop simple parametric models for the imaging process of a SAR.

• Using the scene model and the system model, derive the textural properties of the image parametric form.

• For different scene categories, analyze the effect of imaging system parameters on the features (parameter values) of the image textural patterns.

• For different scene categories, compare the separability of the scene textures with the separability of the textural patterns of the corresponding images.

• For the cases where the comparison could not be done by analytical methods, use simulated imagery to study the effects of the imaging system.
The Influence of Sensor and Flight Parameters on Texture in Radar Images

V.S. Frost, K.S. Shanmugan, and J.C. Holtzman

Remote Sensing Laboratory
University of Kansas Center for Research, Inc.
Lawrence, Kansas 66045

Abstract

Texture is known to be important in the analysis of radar images for geologic applications. It has previously been shown that texture features derived from the grey-level co-occurrence matrix (GLCM) can be used to separate large scale texture in radar images. Here the influence of sensor parameters, specifically the spatial and radiometric resolution and flight parameters, i.e., the orientation of the surface structure relative to the sensor, on the ability to classify texture based on the GLCM features is investigated. It was found that changing these sensor and flight parameters greatly affects the usefulness of the GLCM for classifying texture on radar images.
1. INTRODUCTION

Spectral, textural temporal and contextual features are four important pattern elements used in human interpretation of image data in general and SAR data in particular. Spectral features describe the average band-to-band tonal variations in a multi-band image set, whereas textural features describe the spatial distribution of tonal values within a band. Contextual features contain information about the relative arrangement of image segments belonging to different categories, and temporal features describe changes in image attributes as a function of time. However, when small image areas within, say, a synthetic aperture radar (SAR) image are independently processed on a computer for automated analyses only the tonal and textural features are usually available in making decisions.

In much of the automated procedures for processing radar image data from small areas, such as in crop classification studies, only the average tonal values are used for developing a classification algorithm. Textural features are generally ignored on the basis that the poor resolution of radar imagery does not provide meaningful textural information for such applications since the areal extent of the target is usually small. However, there are many other applications such as the identification of large scale geological formations, land use patterns, etc., where the resolution is more than adequate to provide textural information. Indeed, in these applications, texture is probably the most important image feature. It was previously shown [1] that texture features derived from the grey-level co-occurrence matrix (GLCM) can be used to discriminate texture in radar images. We describe in this paper the influence of sensor and flight parameters on our
ability to quantitatively classify textures in radar images using the GLCM. The effect of spatial and radiometric resolution on texture classification was studied in one experiment. It was found that the classification was very sensitive to these sensor parameters, only the image with the best spatial and radiometric resolutions was quantitatively useful. Another experiment was conducted to determine how different flight paths, i.e., looking at the same terrain from different angles with the same sensor and incidence angle, changed the texture classification. Optical imaging systems rely on the sun to illuminate the scene and thus the sun angle becomes a factor; however, mission profiles for these sensors are usually designed to minimize this effect. For example, the LANDSAT series of sensors uses a high sun angle. On the other hand imaging radars provide their own illumination and it is not clear what effect observing the same geologic structure from different angles will have on the automated analysis.

In the following section the texture features used here to separate different surface structures are briefly described. The sensitivity of these texture features to changes in radiometric and spatial resolution is discussed next. Radar image simulation is then used to evaluate the sensitivity of GLCM texture features to changes in the orientation of the surface structure and the radar. The results of the two studies described in this paper indicate that the usefulness of textural features in automated analysis of radar images is sensitive to changes in the spatial and radiometric resolution of the system as well as the target/sensor geometry.
11. The Texture Features

The textural feature extraction algorithm employed here has been widely used [2-5] for analyzing a variety of photographic images. The procedure is based on the assumption that the texture information in an image block 'i' is contained in the overall or 'average' spatial relationship which the grey tones in the image 'i' have to one another. This relationship can be characterized by a set of grey-level co-occurrence (GLC) matrices. We describe a procedure for computing a set of GLC matrices for a given image block and define a set of numerical textural descriptors (features) that can be extracted from the GLC matrices. These textural features can be used for automated analysis and classification of blocks of radar imagery. Image texture may be viewed as a global pattern arising from a deterministic or random repetition of local subpatterns or primitives. The structure resulting from this repetition could be very useful for discriminating between the contents of the image of a complex scene. A number of approaches have been suggested for extracting features that will discriminate between different textures [2-6]. Of these approaches, it has been found that textural features derived from grey-level co-occurrence matrices (GLCM) are most useful for analyzing the contents of a variety of imagery in remote sensing, biomedical and other applications [7-11]. The GLCM approach to texture analysis is based on the conjecture that the texture information in an image is contained in the overall or average spatial relationship between the grey tones of the image.

The second-order grey-level co-occurrence matrix of an image is defined as follows. Let \( f(x,y) \) be a rectangular digital picture defined over the domain \( x \in [0,n_x), y \in [0,n_y) \), \( x, y \in I \). Let \( n_g \) be the number of
grey levels in \( f \). The unnormalized, second-order GLC matrix is a square matrix \( \overline{P} \) of dimension \( n_g \). The \((i,j)\)-th entry in \( \overline{P} \), denoted by \( \overline{P}_{ij} \), is a function of the image tonal values and a displacement vector \( \overline{d} = (d_1,d_2) \). The entries \( \overline{P}_{ij} \) are unnormalized counts of how many times two neighboring resolution cells which are spatially separated by \( \overline{d} \) occur on the image, one with grey tone \( i \) and the other with grey tone \( j \). That is,

\[
\overline{P}_{ij} = \# \left\{ (m_1,n_1), (m_2,n_2) \mid f(m_1,n_1) = i, \ f(m_2,n_2) = j, \ (m_2,n_2) - (m_1,n_1) = \overline{d} \right\}, \tag{1}
\]

where \( \# \) denotes the number of elements in the set, the indices \( m_1, m_2 \) and \( n_1, n_2 \) take on integer values in the intervals \([0,n_x), [0,n_y)\). The normalized GLC matrix \( \overline{P} \) with entries \( p_{ij} \) is obtained from \( \overline{P} \) by dividing each entry in \( P \) by the total number of paired occurrences. The definition of second-order GLC matrices can be extended to include third- and higher-order GLC matrices. While higher-order GLC matrices may be important in some applications, much of the recent work in texture analysis has been based on second-order GLC matrices.

The second-order GLC matrices are computed for various values of the displacement vector \( \overline{d} \), and features derived from the GLC matrices are used for classifying the contents of an image.

Some of the commonly used textural features derived from the GLC matrix are:
1) Uniformity (sum of squares):

\[ \sum_{i,j} p_{ij}^2 \]  

2) Contrast:

\[ \sum_{i} \sum_{j} (i-j)^2 p_{ij} \]  

3) Correlation:

\[ \sum_{i} \sum_{j} \frac{(l_{ix} - l_{iy})(j_{ix} - j_{iy}) p_{ij}}{\sigma_x \sigma_y} \]  

4) Entropy:

\[ \sum_{i} \sum_{j} p_{ij} \log p_{ij} \]  

5) Inverse Difference Moment:

\[ \sum_{i} \sum_{j \neq i,j} (p_{ij})^6 / |i-j|^u \]  

6) Maximum Probability:

\[ \max_{i,j} p_{ij} \]  

For a variety of imagery (aerial, micrographic and x-ray) the relationship between these textural features, their values and what they represent in terms of visual perception of texture are reasonably well understood. Using features of the form given above, Haralick and
Shanmugan [5-7] were able to classify a variety of images with over 85% classification accuracy. These features have also been used to separate texture in radar images [1].

III. Texture Analysis of SAR Images with Different Spatial and Radiometric Resolution

Numerical descriptions of texture (specifically those derived from the grey-level co-occurrence matrix (GLCM) as in Section II) have been shown to separate some simple geological features [1]. To efficiently design a spaceborne SAR for geologic exploration it is of interest to determine how the ability to separate geological features using the GLCM varies with important system parameters, e.g., spatial and radiometric resolution.

A limited set of radar images with different spatial and radiometric resolutions were obtained (primarily from the Jet Propulsion Laboratory [12]). These images were generated by appropriate processing of the Seasat-A SAR video signal, and were of a geologically interesting area in Tennessee (Figure 1). The specific areas that were studied are outlined in white. The combinations of spatial and radiometric resolution contained in this data set were (25 m, 4 looks), (50 m, 4 looks), (100 m, 4 looks), (50 m, 2 looks), and (50 m, 1 look). Within the Tennessee test area, five distinct textures were identified (see Table 1 for a description of the geology and topography) and five to seven samples of each texture obtained (see Figure 1). A sample of a texture is an image (in this case 3.4 km x 3.4 km in size) containing only one texture type. Thus for each set of sensor parameters 30 texture samples were obtained, a total of 150 texture samples (images)
were used in this study. For each texture sample a GLCM was calculated and texture features found. Specifically, uniformity, contrast, correlation, entropy, inverse difference moment, and maximum probability were the texture features used here. Following [1] the GLCM were calculated for distances of 1, 2 and 4 at angles of 0°, 45°, 90°, and 135°. The above texture features were calculated for each distance and angle. In addition, the average over all angles for each texture feature was calculated. Thus each texture sample is described by a set of 30 numbers (6 texture features, 4 angles, and the average for each feature).

Scatter diagrams of the numerical values for one pair of texture features are shown in Figure 2. These plots are for distance 4 and result from averaging all four GLCM angles. All five textures can be separated using the correlation and maximum probability (Figure 2) features only for the system with a 25 m spatial resolution and with four independent samples averaged. As either the radiometric resolution is degraded (decreased number of independent samples or looks averaged) or the spatial resolution is degraded the ability to separate these textures is also degraded. This same result was found for other combinations of texture features [13]. In all cases only the images with 25 m, 4 looks could be quantitatively used to separate these textures using the GLCM.

This experiment reinforces the conclusions of our previous work [1]: automatically derived texture features can be used to discriminate texture in radar images of rough terrain. Additionally, this study shows that the ability to use the GLCM to classify texture is strongly dependent upon both the sensor's spatial and radiometric resolution.
Even though the data set used for this study was very limited these results do indicate that the usefulness of textural features for radar image analysis is sensitive to the spatial and radiometric resolutions of the sensor. This should be expected because it is well known that for manual analysis the interpretability of radar images is sensitive to the radiometric and spatial resolutions [14-17]. Thus, this study demonstrated that this sensitivity also exists for automatic analysis.

IV. A Study of the Effect of Look Direction On Texture in SAR Images

For an automatic texture analysis system for radar to be successful, a set of texture features must be found which are invariant to the flight path of the sensor. This invariance is clearly needed because the orientation of the terrain features relative to the sensor's flight path is not known a priori. For the geologic analysis of radar imagery where terrain elevation plays a dominant role the imaging geometry of radar would seem to be a dominant factor. Also the question of invariance is important in the search for 'optimum' sensor configurations. For example, it might be possible to classify certain terrain features at one sensor orientation but not at another. However, because the orientation of the sensor to the terrain features of interest will never be known a priori an optimum sensor configuration might not exist.

The purpose of this section is to describe the results of an experiment which was aimed at determining the sensitivity of GLCM texture features, shown to be valuable as a discriminate, to the sensor flight direction, i.e., the target/sensor orientation. It was found
(given the limitations of the experiment) that the texture features considered here could be classified for one or two target/sensor orientations but not for all the three orientations considered here.

To isolate the effect of sensor look direction it was necessary to use radar simulation [18] to create a set of images with controlled terrain and sensor parameters. Further it was possible using the simulation approach to remove (i.e., not include) the effect of speckle [18]. Therefore, this study focused on how shadow, layover, and range compression changed the image manifestations of complex terrain structure as the look direction of the sensor was varied.

In radar image simulation (for a complete description see [18]), the terrain to be analyzed is represented as a two-dimensional integer array referred to as a data base. This array is stored on a file containing fixed-length records. These correspond directly to rows in the array which contain a fixed number of words (columns). This relationship is shown in Figure 3.

The three data bases used in this study were generated from data received from the U.S. Geological Survey in the form of three digital elevation models. These were received containing elevation values which correspond directly to a 1:24000 (1 inch = 2000 feet) topographical map sampled at 30 meter intervals in both the x and y directions. Let x define columns in our data base and y to refer to rows (see Figure 3). In these data x and y both represent 30 meters on the ground. Thus each elevation value was considered to be valid for an area of 30x30 square meters.

The third dimension of the data base, h, represents the elevation of each cell above a given reference elevation. Each increment in
elevation corresponds to \( \Delta h \), which describes a scaling factor for determining the quantization of the actual elevation. In the digital elevation models used in this study, the value for \( \Delta h \) was equal to one meter. This led to a convenient one-to-one relationship for the elevations.

The relationship among the values for \( \Delta x \), \( \Delta y \) and \( \Delta h \) describes the degree to which the elevation changes over an area on the ground. Since only the relative structures of the terrain are of interest in this study, this relationship may be altered as needed. After first removing the reference elevation constant, the data was scaled by 0.25. This allowed the \( \Delta x \) and \( \Delta y \) values to represent 7.5 meters, while the value for \( \Delta h \) remained equal to 1 meter.

The simulation of synthetic aperture radar imagery is made possible through the application of a computer program developed at the University of Kansas Remote Sensing Laboratory [18]. This algorithm will simulate the effects of a spaceborne SAR with a look direction parallel to the rows of the data base array. Since the simulation program always processes the data row by row, the only way to achieve a different look direction is to modify, i.e., rotate, the data base. Keeping this in mind, the unmodified data base is defined to be at a look direction angle of 0°. For this study simulated radar imagery was to be generated for the same areas with look directions of 0°, 45°, and 90°. This required that the data bases be correctly oriented before the simulation was performed. For this, computer programs were applied to rotate the original data in order to simulate different look angles.

Nine data bases were thus available for simulation (3 terrain models at 3 look directions). These nine data bases were then processed using the
simulation program. The radar parameters used for the simulation were similar to those of the Seasat-A SAR. The altitude of the sensor was considered to be roughly 800 kilometers, and the angle of incidence between the sensor and the first cell of the data base was given to be 20 degrees. For the purposes of this study, it was assumed that all of the terrain data was of one scattering category. The scattering coefficient as a function of incidence angle is shown in Figure 4.

Using these parameters along with the assumed value of 7.5 meters for both along-track and across-track resolutions, radar images were simulated, producing the desired set of controlled images. However, these images are now rotated relative to each other. To eliminate the rotational dependence of the GLCM the simulations were converted to one coordinate system.

Visually the effect of changing the flight path is dramatic. Figure 5a-c contains the simulated radar images for one of the digital terrain models. In Figure 5a the sensor's look direction is from right to left. This is our reference direction and is referred to as the 0° look angle. The simulation of a 45° look angle (i.e., from the upper left to the lower right) is shown in Figure 5b and the 90° simulation (i.e., from top to bottom) is shown in Figure 5c. Similarly, Figures 6a-c and 7a-c contain the image simulations for two other digital terrain models. Close analysis of these images reveals many features which are totally obscured by shadow at one look angle but not at the others as was shown in [17]. Also, the spatial structure changes as the look angle is varied from 0° to 45° to 90°.

Beginning with the 0° look direction three distinct spatial structures, textures, were identified.
TEXTURE 1 contained low relief with some small hills and ridges, maximum relief is about 100-300 feet.

TEXTURE 2 contained elongated ridges and mountains usually separated by steep gradient streams, maximum relief is about 500-700 feet.

TEXTURE 3 contained long, narrow valleys with steep slopes and depths of about 300-400 feet. Valley streams have medium to low gradients.

From each texture, 3 or 4 samples (subimages) were obtained. The same subimages were then sampled from the 45° and 90° look direction simulations. A total of 33 subimages provided the input for this experiment (11 subimages for each look direction). These subimages are shown in Figure 8a-c. The specific research questions addressed by this experiment were (1) can these three textures be classified using GLCM features at any of the three look directions, and (2) can these three textures be classified using GLCM features independent of the look direction, i.e., are the texture features derived from the same spatial structure independent of the look direction of the sensor, thus, can the textures be classified using all three orientations simultaneously.

For each of the 33 subimages described above a GLCM and the resulting texture features were calculated for distances of 4, 6, and 10 at 0°, 45°, 90°, and 135° (these angles will be referred to as GLC angles as opposed to the look direction angle). It was found [13] that distances 4 and 10 showed basically the same trend as 6 so only the distance 6 results will be discussed. Also, it was found that averaging the texture features over the GLC angle as was done previously [1]
destroyed our ability to separate textures one and two. This is expected from their spatial structure. Thus only results from individual GLC angles will be presented. The GLCM texture features were analyzed pair-wise as was also done previously [1].

Analysis of the data qualitatively showed that all three textures could be classified at one or two target/sensor orientations but not at all three simultaneously. For example, Figure 9a-c contains the scattergrams for the maximum probability and contrast texture features at GLC distance 6 and GLC angle of 0°. At a look direction of 0° (Figure 9a) none of the three textures can be separated, while at 45° (Figure 9b) all three textures can be classified. Analysis of other texture pairs shows the same trend, i.e., the textures considered here can be classified for one or two sensor look directions but not at all three [13]. If the texture samples for each terrain structure from all three look directions are combined it becomes obvious that the textures considered here cannot be classified independent of look direction (see Figure 10a-e).

The purpose of this analysis was to determine the sensitivity that GLCM texture features show to changes in the orientation of the surface structure relative to the sensor. Radar image simulation was used to generate a suitable set of images with the effects of the sensor flight path isolated. Within the limitations of this experiment, i.e., three different terrain structures, and three flight directions, it was shown that (1) the GLCM texture features can be used to classify the terrain structures at one or two flight directions but not at all three, and (2) the GLCM texture features cannot be used to classify these terrain structures independent of the flight path. The search of the optimum
set of sensor parameters for geologic applications is thus complicated. That is, the results of this study indicate that the optimum sensor for classifying (using either manual or automatic techniques) surface structure is dependent upon the orientation of the structure to the flight path of the sensor. Because of the monostatistic nature of radar imaging the same surface structure imaged at two different flight angles can (and often do) appear totally dissimilar. A set of sensor parameters optimized to detect these structures at one flight angle might be totally different if the flight angle were changed.

V. CONCLUSIONS AND RECOMMENDATIONS

Texture is an important characteristic of radar images of rough terrain. It was shown that the GLCM derived texture features can be used to classify texture. In this paper we have demonstrated that GLCM derived texture features are sensitive to both sensor and flight parameters. In fact, we lose our ability to classify texture by these features if either the radiometric or spatial resolution is degraded. We also found that these texture features are sensitive to the sensor flight path. We could classify the surface structure for one or two target/sensor orientations but not for all three considered simultaneously. That is, GLCM texture features cannot be used to classify texture independent of the flight path.

While general conclusions on the sensitivity of textural features to system and flight parameters can be made from the results of this study, there is a need to further refine these conclusions, specifically. It is recommended that the sensitivity shown here be quantitatively studied. Quantitative results are needed to help guide system design.
and flight planning. Two approaches to obtaining quantitative results should be pursued in parallel. First, an analytic study of the relationships among surface, sensor and flight parameters and the GLCM is needed. Second, more radar images should be analyzed. With more data the qualitative discussion of the effects of spatial and radiometric resolution can be extended to a quantitative analysis, for example plots of the 'variance' of each cluster as a function of resolution could then be studied. The ultimate goal of such an analysis would be an expression for the sensitivity of each texture feature as a function of resolution. This study also dealt with only radical changes in the flight direction over a fixed site. Further analysis is now needed to determine the effect of small angle changes, e.g., on the order of 5°. Also this study only considered one angle of incidence. It would be interesting to determine if there exist some incidence angle for which we could classify surface structure independent of the flight angle.

ACKNOWLEDGMENTS

The authors are indebted to the individuals who have contributed to this study, Dr. Josephine Stiles and Mr. Scott Gardner. Also, thanks are expressed to Dr. Dan Held of the Jet Propulsion Laboratory for supplying the SEASAT-A SAR data.

3. APPLICATION TO THE DESCRIPTION OF NATURAL IMAGES

In this section we will discuss an application of the procedures described in the preceding section to the description of a set of real textures. As described in the introduction, the problem is to detect trees in aerial photographs of citrus groves, and then to classify the trees as being either healthy or infested. We are concerned here only with the process of tree detection. We will detect trees by first detecting a set of "obvious" trees, and then using the locations of those trees as input to the processes described in the preceding section. These procedures will predict the locations of other trees in the image; these locations can be used by subsequent programs to detect and classify trees not found by the first stage.

The procedures for detecting trees consists of differentiating the image and then using a Hough transform (Kimme et al. [11], Shapiro [12]) to find tree centers in the differentiated image.

Fig. 7. Digitized 64 x 64 orchard image.

Fig. 8. Circle centers for Fig. 7.
3. Arbitrary Shapes (Ballard, Davis and Yam)

\[ B(S) = \left\{ (\Delta X_i, \Delta Y_i) \right\}_{i=1}^n \]
\[ P = \left\{ (X_i, Y_i) \right\}_{i=1}^n \]

a. Position invariant matching (Sklansky)

For each \((X,Y) \in P\) do

for each \((\Delta X, \Delta Y) \in B(S)\) do

\[ H(X+\Delta X, Y+\Delta Y) = H(X+\Delta X, Y+\Delta Y) + 1 \]
Computationally equivalent algorithm:

For each \((X, Y)\) in \(f\)

For each \((AX, AY)\) in \(B(S)\)

\[
H(X-AX, Y-AY) = H(X-AX, Y-AY) + \Theta f(X, Y)
\]

\[
\{ H(X, Y) = H(X, Y) + f(X+AX, Y+AY) \}
\]

Algorithm (1) - \(o(m-n)\) operations

Algorithm (2) - \(o(rsm)\) operations
b. Rotation invariant matching

- only the magnitude of the vectors in B can be used

For each \((X,Y) \in P\) do

For each \((AX,AY) \in B(S)\) do

For \(\epsilon = 0, 2\pi, 4\pi \) do

begin

\[ X' = X + AX \cos \epsilon \]
\[ Y' = Y + AY \sin \epsilon \]
\[ H(X', Y') = H(X', Y') + 1 \]

end

- each pair \(((X,Y), (AX,AY))\) is used to paint out a circle

in \(H\).
c. Scale Invariant matching \( (S_1, S_2) \)

For each \((X,Y) \in P\)

For each \((\Delta X, \Delta Y) \in B(S)\)

For \( S = S_1, S_2, 4S \)

begin

\[ X' = X + S \Delta X \]

\[ Y' = Y + S \Delta Y \]

\[ H(X', Y') = H(X', Y') + 1 \]

end
Generalized Hough Transforms

$\mathbb{R}^n \xrightarrow{f} \mathbb{R}^m$

$P \xrightarrow{f} Q$

$P$ - pattern of interest

$Q$ - pattern of detected features

$P = \{ p_1, ..., p_m \} \subseteq \mathbb{R}^n$

$Q = \{ q_1, ..., q_s \} \subseteq \mathbb{R}^m$

$f(P) = \{ f(p_1), ..., f(p_m) \}$

Goal: Find $f \in \mathcal{F}$ such that

$n(E) = \# (Q - f(P))$ is minimal
Ordinarily:

\[ \mathcal{F} \] is defined by a set of parameters \\
\{ t_1, \ldots, t_n \}

**Example:**

\[ \mathcal{F} : \mathbb{R}^n \rightarrow \mathbb{R}^n \]

\[ f_{t_1 t_2} \in \mathcal{F} \] is defined by

\[ f_{t_1 t_2}(x, y) = (x + t_1, y + t_2) \]

- For computation, \( \mathcal{F} \) is reduced to a \( \mathcal{F}' \), a finite subset, by

1) restricting the domains of the \( t_i \)

2) quantizing the resulting restricted domains.
Key to the efficiency of the GHT is the ability to efficiently enumerate certain subsets of $\mathcal{F}$.

Let $p \in P \\ q \in Q$.

Define: $\mathcal{F}_{pq} = \{ f \in \mathcal{F} \mid f(p) = q \}$ $\subseteq \mathcal{F}$

In practice, we deal with $\mathcal{F}'$

$\mathcal{F}'_{pq} = \{ f \in \mathcal{F}' \mid \text{dist}(f(p), q) \leq \varepsilon \}$

where $\varepsilon$ is a constant determined by the quantization of the $t_i$. 
Example of enumerating \( \mathcal{F}_{pq} \)

\[ P, Q \subseteq \mathbb{R}^2 \]

\[ \mathcal{F} : \{ f_0, ax, ay \} \cup \{ f_0, ax, ay \mathcal{F}(x,y) = \\
\begin{cases}
(\cos \theta + \sin \theta + ax, -\sin \theta + \cos \theta + ay)
\end{cases} \]

Given \( p \in P \), \( q \in Q \), how do we enumerate \( \mathcal{F}_{pq} \)?

1) Efficient procedure: For each quantization level of \( \theta \), compute all \( ax, ay \) s.t.

\[ |f_0, ax, ay (p) - q| < \varepsilon \]

2) Inefficient: For each \( (ax, ay) \)

compute all \( \theta \) s.t. ...
(Ballard)

Procedure \textsc{GHT1} (P, Q, \pi; H)

For each \( p \in \mathcal{P} \)

For each \( q \in \mathcal{Q} \)

Compute \( \mathcal{F}'pq \)

For each \( f_{t_1}, \ldots, t_u \in \mathcal{F}'pq \)

\[
H(t_1, \ldots, t_u) := H(t_1, \ldots, t_u) + 1
\]

\text{endf}

\text{endf}

\text{endf}

\text{endf}

\text{end} \mathcal{P}

After \textsc{GHT1}

\[
H(t_1, \ldots, t_u) = \#(\text{ANS}_{t_1, \ldots, t_u}(P))
\]

Therefore, the \( f \) which maximizes \( H \), minimizes \( v \).
Representing high-dimensional Hough arrays

1. Coarse-to-fine quantization

2. Multiple projections
Tree-structure (k-d trees)

- sequence through parameters one level at a time

- nodes are split if points within node are not "uniformly" distributed

- nodes are merged to increase uniformity
Figure 4a: 2-d quantized space

Figure 4b: 2-d tree structure
Hierarchical Hough Transforms

Given a pattern of points $P$, compute all Level 0 Hough transforms: $H_{01}, H_{02}, H_{03}, H_{04}$.

Let $M_i$ be the set of above-threshold peaks in $H_{0i}$, $i = 1, \ldots, 4$.

Compute the Hough transform at Level 1 with the sets $M_i$ for each $c_i$ in Level 1.

For each $m_j$ in $M_i$ increment the appropriate subspace of $HT$. 
Interest Points in Fract 1
Hough Transform for linear pattern

- \( L = \{ L_1, \ldots, L_n \} \) - set of line segments which define the pattern
- \( L' = \{ L_1', \ldots, L_m' \} \) - set of observed line segments.

Define \( L_i - L_j \) as follows

- If \( L_j \) is a subsegment of \( L_i \), then \( L_i - L_j \equiv L_j - L_i \)
- Otherwise, \( L_i - L_j \equiv L_i \)

Let \( \mathcal{F} \) be a set of transformations that map lines to lines.

Matching problem

Given \( L, L' \), find \( f \in \mathcal{F} \) s.t.

\[
\nu(f) = \sum_{L_i \in L} \sum_{L_j' \in L'} [L_i - f(L_j')]
\]

is minimal.
Figure 6 (ii)
Subpixel Registration Accuracy
and Modelling

Laveen N. Kanal
LNK Corporation
INTRODUCTION

• HOW ACCURATELY CAN A LANDSAT IMAGE BE REGISTERED TO A REFERENCE IMAGE?

• HOW CAN SUBPIXEL ACCURACY BE ACHIEVED?

• WHAT FACTORS AFFECT REGISTRATION ACCURACY?

• HOW SHOULD THE REFERENCE IMAGES BE FORMED?

• HOW CAN VARIOUS ALGORITHMS BE EVALUATED?
HIGH REGISTRATION ACCURACY

- Needed to merge data from different sources
  - Multitemporal data
  - Multisensor data

- Misregistration results in reduced classification accuracy
TYPICAL REGISTRATION REQUIREMENTS

- LESS THAN .5 PIXEL GEODETIC REGISTRATION ERROR

- .3 PIXEL RELATIVE (BETWEEN TWO IMAGES)

Above standards must be met 90% of the time.
CURRENT REGISTRATION APPROACH

- Develop Control Point Chip Library (CPC)
  - CPC-set of recognizable points

- Extract Control Point Neighborhood (CPN) from scene to be registered

- Find best location in CPN matching CPC
SUBPIXEL REGISTRATION ACCURACY

Basic Problem: Find a translation aligning a reference (Ground Control Chip) and a Landsat image to less than one pixel.
SUBPIXEL ACCURACY PROBLEMS

1) WHAT IS SUBPIXEL ACCURACY?

Image distortion is nonlinear.

MEASURE OF ACCURACY? Maximum error, average error, percentage of points lying far away?

2) HOW CAN CLAIMS FOR SUBPIXEL ACCURACY OF ALGORITHM BE ASSESSED?

- Experimental methods
- Analytical methods
  - Probabilistic image models for correlation procedures
  - Geometric models for feature (edge) matching
    - Assume error bounds on feature detection
    - Compute bounds on estimation of edge location
PROBLEMS (Cont'd.)

3) WHAT SCENE PROPERTIES SHOULD BE USED TO SELECT GROUND CONTROL CHIPS FOR AN IMAGE?

4) HOW SHOULD THE LANDSAT IMAGE BE PROCESSED TO FORM AN IMAGE SUITABLE FOR MATCHING?

- Edge enhanced image
- Edge image
- Isolated significant point image
  - Corners
  - Intersections
  - High curvature points
CLASSICAL CORRELATION

\[ R(u,v) = \frac{\sum_{j=1}^{K} \sum_{i=1}^{J} S(i,j)W(1-u,j-v)}{\left( \sum_{j=1}^{K} \sum_{i=1}^{J} S^2(i,j) \right)^{\frac{1}{2}} \left( \sum_{j=1}^{K} \sum_{i=1}^{J} W^2(1,j) \right)^{\frac{1}{2}}} \]

Can be applied to Landsat image, edge enhanced image, binary image, etc.

One dimensional example

Image 1  Image 2  Correlation
CORRELATION SURFACE QUALITY
MEASURES

- Peak to sidelobe ratio

- Curvature of the peak
BASIC SUBPIXEL REGISTRATION APPROACH

- Find the cross-correlation between a CPC and the corresponding CPN

- Interpolate the correlation function to find the continuous correlation surface peak

CPC and CPN may be preprocessed to improve correlation accuracy.
INTERPOLATION FOR SUBPIXEL ACCURACY

1) Fit surface to correlation function in a neighborhood.
   - 5x5 neighborhood is common
   - Up to the 4th order bivariate polynomials are used
   - Successive orders can be used, use RMS residual error to select order
   - Elliptical cones have been used

PROBLEM:

Sensitivity of peak location to fitting function
INTERPOLATION (Cont'd.)

2) Use centroid of correlation function in a neighborhood

3) Spatial offset corresponds to non-vanishing phase in frequency domain
   - Transform phase portion of correlation back to spatial domain to locate peak

PROBLEM:
Non symmetry of cross-correlation function about peak causes error in phase
ESTIMATING CORRELATION PEAK

UNCERTAINTY

1) Curvature at peak

2) Second moment of correlation samples around peak

3) Rate of decline away from peak

USES OF MEASURES:

- Reject Matching

- Weight for mapping function fit.
FEATURE IMAGE MATCHING

FEATURES

EDGES

INTERSECTION

HIGH CURVATURE POINTS

- Feature matching is growing in popularity
- Robustness under spectral change
  - Crop growth
  - Water content
  - Illumination
METHODS OF FEATURE MATCHING

- Correlation of Edge Images

- Correlation of Binary Edge Images

- Lineals Correspondence (L.N.K. procedure)
  - Real lineals
  - Abstract vectors

- Point Matching
  - Relaxation
LITERATURE INTRODUCTION

- Review five previous studies of Landsat registration accuracy
- Common flaw - reference image assumed highly accurate
- Some sources of reference image accuracy
  1) Polynomial fitting on enlarging reference image to match map
  2) Fitting polynomial to determine attitude and altitude correction
- Combined error effects estimated accuracy ¼ pixels
  - 90% of all points had positional error within 23 meters (Niblack 1981)
  - Basis for above not adequately described in paper.
DEPARTURE FROM PREVIOUS EXPERIMENTS

- Previous theoretical and simulation studies of registration accuracy measure performance in one of two ways:
  
  (1) Single offset probability of false acquisition to determine accuracy to nearest pixel, and
  (2) Either expected value of the error or root mean square of the error, to measure subpixel accuracy.

- We propose to replace the above by the following:
  
  (1) Probability of false acquisition over the entire image, and
  (2) The probability distribution of the error.
EXPERIMENTAL REGISTRATION

PURPOSE - DETERMINE FEASIBILITY AND EXTENT OF SUBPIXEL ACCURACY OF EDGE LOCATION UNDER IDEAL CIRCUMSTANCES.

METHOD: GENERATE A REFERENCE IMAGE CONSISTING OF TWO HOMOGENEOUS REGIONS

- θ IS A PARAMETER
- THE TWO REGIONS HAVE DIFFERENT MEANS AND I.I.D. PIXELS
- SENSOR IMAGE CONSISTS OF A SUBPOINT OF THE REFERENCE IMAGE WITH NOISE ADDED
- GREY LEVEL CORRELATION USED TO MATCH IMAGES
- FOURTH-ORDER BIVARIATE POLYNOMIAL FIT TO CORRELATION IN A 5x5 NEIGHBORHOOD
- PEAK TAKEN AS MATCH POINT

NOTE: NO TRANSLATION WAS INTRODUCED. EFFECT OF NOISE ON OFFSET WAS DESIRED.
EXPERIMENTAL RESULTS

OUTCOME:

• Correlation function turned out to be almost circularly symmetric

• Estimated peak always near center of pixel

• Peak is estimate of where corner lies within pixel

• True corner was often near pixel boundary

• Subpixel accuracy was poor

• Window size (225 pixels) was large enough to make Law of Large numbers applicable

• Numerator and denominator of correlation function change little in neighborhood of correct match point, thus explaining symmetry

• Future experiments will assume noise points are correlated and reference points are correlated (not independent)

• This will alleviate the above problems and make simulations more realistic.
COMPARISON OF OUR SIMULATIONS WITH NOVAK'S

- Novak's work did better than ours since he only considered a small strip around the edge
  - Here a pixel shift in the template causes a large difference in the statistic

- Combination of Novak's simulation and ours gives insight into matching problem
  - Maximum likelihood makes most efficient use of data
  - From this viewpoint Novak method poor for finding edge to nearest pixel
  - One should use full control chip since maximum likelihood estimate uses all pixels.

- Subpixel Accuracy
  - Maximum likelihood for subpixel accuracy uses only edge pixels
  - Other pixels add no information - only cause further error
  - Novak's method superior here
COMPARISON WITH NOVAK'S METHOD (cont'd.)

• Conclusion (tentative)

- Perform correlation on whole control chip to get pixel accuracy
- Only use pixels with a high likelihood of sub-pixel information (e.g., on or near edges) for subpixel matching.
MOSTAFAVI-SMITH MODEL

\[ l_r = p(x) + n_r(x) \]

\[ l_s = p_d(x) + n_s(x) \]

\[ p_d(x) = p(Ax + x_0) \]

\[ x = (x_1, x_2)' \quad \text{point in plane} \]

\[ A: \quad \text{2x2 distortion matrix} \]

\[ p: \quad \text{noise free image either a deterministic} \]
\[ \quad \text{or a random signal} \]

For \( p \) deterministic, \( p(x), p_d(x) \) or their Fourier
Transfoms available. For \( p \) random: signal spectrum
assumed known \( p, n_r, n_s \) zero mean, 2nd order, inde-
pendent Gaussian Processes with spatially invariant
statistics.
MOSTAPAVI-SMITH MODEL FOR REGISTRATION

GOAL: Find image size and shape minimizing probability of false acquisition and maximizing local accuracy.

MEASURES OF CORRELATOR PERFORMANCE

1. Ratio of mean cross-correlation peak to standard deviation of cross-correlation in the sidelobes (called Peak-to-Sidelobe Ratio).

2. Probability that the correlation function of some point far from the correct registration exceeds some threshold. (called the single-offset probability of false acquisition.)

3. First order approximation to local registration error using the correlation function gradient and curvature.

BASIC ASSUMPTIONS: Gaussian images, additive Gaussian noise, the two images to be registered are related by an affine transformation.

RESULTS

1) Derives image size to minimize probability of false acquisition under geometric distortion.

2) Derives expression for minimum achievable probability of false acquisition.

3) For circularly symmetric autocorrelation functions, the square window is optimal among rectangle windows.

4) Derives optimal window size to maximize local accuracy.

5) For a fixed geometric distortion the image size resulting in minimum local error is smaller than the size giving a minimum probability of false acquisition.
FUNDAMENTAL ASSUMPTIONS

MOSTAFAVI-SMITH (1978)

REFERENCE IMAGE $I_R(\chi)$ SPATIALLY STATIONARY

Sensed image $I_S(\chi)$

$$I_S(\chi) = I_R(\theta+\chi) + I_N(\theta+\chi)$$

NOISE INDEPENDENT OF $I_R$, $I_R$, $I_N$ GAUSSIAN

Comments

RETAINED ONLY TRANSLATIONS, NOT DISTORTIONS, CONSIDERED NOW

NEED ONLY $I_R$, $I_S$ JOINTLY STATIONARY ALTHOUGH INDEPENDENT CASE IS SIMPLEST NOT NEEDED AT ALL

* STATISTICS SPATIALLY SHIFT-INvariant

** ADDITIVE NOISE UNREALISTIC ESPECIALLY FOR PREPROCESSED OR EDGE-ENHANCED OR BINARY PICTURES

*** SINCE WEAK ASSUMPTIONS ON $I_R$, $I_S$ GUARANTEE THE CORRELATION PROCESS $C(\chi)$ AT VARIOUS OFFSETS $\chi$ IS ESSENTIALLY GAUSSIAN FOR LARGE WINDOWS (SENSED IMAGES).
DEFINITIONS

\[ D(x) = E \{ C(x) \} \]

**Picture of one-dimensional case**

\[ D(x) \text{ "known" for } x = 0, \pm H, \pm 2H, \ldots \quad H = \text{pixel width} \]

\[ \theta^* = \text{estimated (from } C(\cdot))\text{ maximum location} \]

**Figure of merit**

\[ Q(T) = \Pr \{ |\theta^* - \theta| > T \} \]

\((+) \text{ note distinction from single-offset comparisons like } \Pr \{ C(0) > C(x) \} \text{ for various } x, \text{ as used by Mostafavi-Smith (1978)}\)
ACCURACY BOUND

If \( D(x) \) is known at
\[ 0, \pm H, \ldots, \]
and if observed pixel grey-level is
\[ X_k = \frac{1}{H} \int_{KH}^{(k+1)H} I_s(t) \, dt \]
(or any other linear operator of \( I_s \))

with reference-image pixel grey-level
\[ Y_j = \frac{1}{H} \int_{JH}^{(J+1)H} I_R(t) \, dt \]

Then a right upper bound on the error as a fraction of a pixel is
\[ K = \left( \frac{H^2 D'(t)(\theta)}{-12D''(\theta)} \right)^{\frac{1}{2}} \]

Qualitative meaning and interpretation of \( K \):

(A) If \( D(x) \) is known at integer multiples of \( H \), then treating \( D(') \) as quadratic on pixel containing \( \theta \) gives error at most fraction \( K \) of pixel.

(B) If \( I_R \) is highly oscillatory with respect to unit of length \( H \) with correlations of \( I_R' \) falling off rapidly then \( K \) is large.
EDGE SUBPIXEL ACCURACY

• Assume relatively high correlation accuracy (within a pixel or two)

• Locate edge in image known to correspond to straight features

• Estimate location of line in mixed pixels
1) Make distributional assumptions for bordering regions.
   - Estimate mixed pixel values for each possible location of line
   - Use optimization to pick line best fitting grey level data

2) Find best line fitting pixels ignoring grey levels

Example: Fit line through centers
BASIC QUESTIONS:

- How accurately can we locate real world edges and strips given observed digital edges and strips?

- How can this accuracy information be used to achieve subpixel accuracy?

- What properties of lines or strips can be used to select good features for a reference image?
TYPES OF OBSERVED EDGES

1) Digital edge - the set of pixels a real edge intersects
   • Simplest model but unrealistic

2) Digital edge (pixels missing) - any subset of a digital edge
   • Feasible model if we only select good candidates for edge points

3) Digital edge (pixels missing, pixels added) - a digital edge with some pixels missing and some spurious edge pixels added
   • Realistic model
Domain of Variability

The set of observed edge pixels resulting from a real edge could come from an infinite number of edges.

Problem: How can we parametrize the possible lines causing these edge pixels to be observed?
Digital line description
(Dorse and Smeulders)

Digital lines will be characterized by four parameters.

Eight connected lines are used.

Chain code

\[ \text{Chaincode 0100} \]

Four parameters:
- \( N \) - Length of chain code
- \( Q \) - Smallest periodicity present in string
- \( R \) - Number of codes per period
- \( S \) - Starting point of segment with standard period
Given a digital edge, the set of all lines which could give rise to the edge can be parametrized in terms of \((e, a)\).

- Feasible region is a quadrilateral.
- Vertices can be expressed in closed form in terms of \((N, q, p, s)\).
If one defines functions \( F \) and \( L \) by:

\[
F(s) = s - \frac{H_t}{q},
\]

and

\[
L(s) = s - \frac{H_t}{q},
\]

and an integer \( t \) by the implicit definition

\[
1 + \lfloor t^2 \rfloor - \frac{t^2}{q} = \frac{1}{q} \quad \text{and} \quad 0 < t < q
\]

THEN THE CORNERS \( A, B, C \) AND \( D \) OF A DOMAIN IN \((e, o)\)-COORDINATES ARE GIVEN BY:

\[
A = \left( \frac{F(s)^2}{q} - \frac{F(s)P^2}{q^2}, \frac{P^2}{q^2} \right)
\]

\[
B = \left( \frac{F(s)^2}{q} - \frac{F(s)P^2}{q}, \frac{P^2}{q} \right)
\]

\[
C = \left( -\lfloor F(s^2) \rfloor - \frac{F(s^2)P^2}{q}, \frac{P^2}{q} \right)
\]

\[
D = \left( -\lfloor F(s^2) \rfloor - \frac{F(s^2)P^2}{q^2}, \frac{P^2}{q^2} \right)
\]

where

\[
q_\pm = L(s^\pm) - F(s), \quad p_\pm = (pq_\pm^2) / q
\]

\[
q_\pm = L(s) - F(s^\pm), \quad p_\pm = (pq_\pm - 1) / q
\]
Feasible Parameter Region

Digital Edge - Pixels Missing

For simplicity assume $0 < \text{slope} < 1$

- Each feasible line intersections diagonal line with slope -1 through selected pixels
- Select distances along diagonal in leftmost and rightmost pixels as parameters of line
- Each intermediary diagonal gives rise to at most two linear inequalities restricting the feasible region
- Feasible region is a polygon in the $(a, b)$ plane
FEASIBLE PARAMETER REGION

DIGITAL EDGE - PIXELS MISSING, PIXELS ADDED

- Each subset of pixels through which a line can pass gives rise to a convex polygon
- Feasible region is union of these polygons
- Combinatorial problems make one of the following restrictions desirable:
  1) Few wrong pixels added
  2) Few pixels total
  3) Approximation of feasible regions
- Careful thresholding and edge checking may help achieve the first two restrictions
- Approximation of feasible region:
  - Fit least square line through edge points
  - Discard pixels not on fitted line
  - Apply analysis of case where no pixels are added
  - If necessary perturb the line and repeat the process
- Weight polygons by the number of corresponding edge points
Digital Edge

Feasible region - quadrilateral

Digital edge (pixels missing)
- Assume n pixels given
- Feasible region convex polygon with at most 2n sides
VARIATION MEASURES

Y VARIATION GIVEN X

Y VARIATION GIVEN \( x_0 \)

\[ \text{ENVELOPE OF FEASIBLE LINES} \]

X VARIATION GIVEN Y IS DEFINED SIMILARLY
Parametrize each feasible line segment to have unit length.

Define variation function $V: [0, 1] \rightarrow \mathbb{R}^+$ by $V(t) =$ maximum distance between feasible lines, measured $t$ units down each line.
VARIATION MEASURES (CONT'D.)

VARIANCE OF $y$ GIVEN $x$

VARIANCE OF $x$ GIVEN $y$

VARIANCE OF POINT $t$ UNITS DOWN EACH LINE
DISTRIBUTIONS ON LINES

- Many distributions on lines are feasible
- Uniform distribution depends upon the parametrization
- Invariance under rotation and translation singles out a distribution:

Uniform distribution in $(p, \theta)$

WHERE THE DISTRIBUTION IS OVER ALL LINES PASSING THROUGH A GIVEN BOUNDED FIGURE
STATISTICS OF Y-VARIATION

- Let $x_0$ be fixed
- Find the mean and variance of the $y$ values of the feasible lines at $x_0$
- Find a confidence interval for the $y$-coordinate being within a specified distance from the mean
- Mean and variance can be calculated easily numerically
- We are working on confidence intervals
VARIATION GOALS

1) Derive bounds for each variation measure as a function of digital edge parameters

2) Compute the mean and variation of each variation measure

3) Find the x, y or f value which minimizes the corresponding variation measure

4) Find good digital edge characteristics, e.g., slope which can be used to minimize variation measures
Assume we have two real line segments sharing an end point

\[ t \in \mathbb{T} \]

- How can we use this knowledge to refine our estimation of positions?
- What angles are best for estimation?
- What can be done if the line segments don’t intersect?
ANGLE CONSTRAINTS

Assume we observe the digital edges resulting from a real angle.

We get a feasible region for each real line segment:

- A feasible angle is a pair of points one in each feasible region.
- Common vertex implies both point lie on same vertical line.
- Fixed angle implies distance between two points is constant.
- Let $\alpha_0$ denote this distance.

Feasible region = \{(e, \alpha) \in R_1: \text{there exists a point } (e, \beta) \in R_2 \text{ with } \beta - \alpha = \alpha_0\}
ERROR BOUNDS ON POINT MATCHING

- Each edge gives rise to a point to be matched with a point in the reference image.

- What can be said about the accuracy of the estimated transformation given the bounds or statistics of the individual point location accuracies?

- Work on this problem will be performed when we have finished our estimates for the point accuracy with digital edges (pixels missing).

- Final result:
  
  Error bounds on transformation accuracy given observed edges.
EXPERIMENTAL CORRELATION STUDIES:

• Simulation results indicate that correlation and surface fitting to attain subpixel accuracy should be based on pixels likely to carry substantial subpixel information (near edges).

• Future simulations will be more realistic and will study the above phenomenon in more detail.

ANALYTIC STUDY OF PROBABILISTIC SUBPIXEL ACCURACY:

• Two models were developed
  1) Error effect due to quantization when reference image is random
  2) Error effect with deterministic image (known shape) due to fitting error

GEOMETRIC ERROR ANALYSIS:

• Feasible parameter regions for lines passing through sets of pixels have been obtained

• Expressions for maximum x,y variation and means and variances have been developed.
PROGRESS AND FUTURE WORK (CONTD.)

GEOMETRIC ERROR ANALYSIS (CONTD.)

- Constraints on feasible regions imposed by angles have been derived

- Evaluation of the above estimates to derive optimal features and quality measures of features are underway

- We are currently attempting to derive a formula for the feasible region in a digital edge with pixels missed

- The effects of the above estimates of point location accuracy on registration transformation accuracy will be studied

- Effects of geometric distortion on the above analysis will be studied.
Improving Spatial Modelling in Remote Sensing

Hunter College:
A. H. Strahler
C. E. Woodcock
Assisted by R. Irish

U. C. Santa Barbara:
J. R. Tobler

Definitions

Sensor: Device that measures intensity of EMR

IFOV (Instantaneous Field of View): Field of view over which the EMR is integrated by the sensor.

MTF (Modulation Transfer Function): Describes way in which EMR in IFOV is integrated to produce a measurement.

Measurement: Output of a sensor in response to this integration. Usually digital, in our case.

Scene: Spatial & temporal distribution of matter and energy fluxes from which the sensor draws measurements.

Image: Collection of measurements produced by a sensor that are arrayed in a systematic fashion derived from the spatial or temporal position from which they were collected.
Resolution Cell: Average rectangular area of a scene that is associated with each measurement.

Structure of Model

- Real scenes are not chaotic, but possess order, at least to some extent.
  -- Only certain combinations of energy and matter occur.
- Energy flux incident upon & emitted from scene passes through atmosphere.
  -- Back scattering, multiple scattering, etc.
- Sensor will measure EMR flux imperfectly.
  -- Calibration; nonlinearities, etc.

Leads to concept of trace components to RS Model ....
Three Components of Remote Sensing Model

1. Scene Model: Specifies form & nature of energy & matter within the scene & their spatial & temporal order.

2. Atmospheric Model: Describes the interaction between atmosphere & energy incident on/exiting from the ground scene.

3. Sensor Model: Describes behavior of the sensor in response to energy fluxes incident upon it & in producing the measurements that constitute the image.
FUNDAMENTAL REMOTE SENSING PROBLEM:

Inferring the order in the properties and distributions of energy and matter in the scene from the set of measurements that comprise the image.

- Scene inference always implies the application of a remote sensing model
  - Assumptions always made concerning ground scene, atmosphere, & sensor

- Scene inference is thus a problem of model inversion in which the order in the real scene is reconstructed from the image & the remote sensing model.

- This research focuses on the scene model
  - Transparent atmosphere
  - Perfect sensor
Background: Is spatially continuous by uniform elements. Examples: Soil, snowy, rocks, underfoot.

Typically, a scene will contain several elements.

- Airplane, runway, truck, pool
- Leaf, branch, plant, row, tree, field, stand

Examples:

- Leaf, branch, plant, row, tree, field, stand
- Airplane, runway, truck, pool

Or stochastic & characterized by distribution parameters (e.g., heat capacity, conductivity, emissivity, etc.)

Element: Abstraction of class of real objects having uniform properties or parameters.

Components:

- Propriety may be fundamental and invariant.
- Or stochastic & characterized by distribution parameters (e.g., heat capacity, conductivity, emissivity, etc.)
Energy Fluxes Into Scene: Characterized by wavelength, intensity, polarization; distributed hemispherically.

- Passive systems: Typically assume incoming flux characteristics are spatially and temporally stationary.
- Active systems: Flux characteristics a function of source-sensor relationship.
Types of Scene Models

H-Resolution: Resolution cell smaller than elements.

L-Resolution: Resolution cell larger than elements.

Deterministic: Utilizes basic physical laws concerning interaction of matter & EMR.

- Includes emissivity, scattering, etc., of elements as properties or parameters.
- Utilizes principles of conservation of energy & matter (e.g., radiative transfer equation) and/or laws of thermodynamics.
- Often L-Resolution.

Empirical: Associates observed sensor measurements with scene elements

- Typically statistical.
- Typically H-Resolution.

Actually, D. & E. are endpoints of a continuum.
Invertibility

Remote sensing models are usually invertible because they are constructed for scene inference.

- **Manual Photointerpretation**: Inversion of a model in the mind of the photointerpreter.

- **Automatic**: Explicitly invertible by virtue of side constraints.
  - E.g., maximum likelihood.
Variance Vs. Resolution Cell Size

Example: Conifer Forest

Tree Crown Size

Colorado Scene - digitized @ true scale of ~ 1.5 m.

Ag. Image - digitized @ true scale of 15 cm
Theory of Regionalized Variables (TRV)

- Looked to Spatial Statistics to build bridge between scene model and image variance/resolution concept.

Regionalized Variable: Random variable with an associated position in time or space.
- Considerable theoretical work done in past twenty yrs, esp. in Geology.
- Simple, basic approach.

Theoretical Framework
- \( Y(\xi) \) is R.V. associated with spatial position \( \xi \).
- E.g. - digital image, where \( \xi_i, i=1, \ldots, n \) correspond to resolution cells
- If \( Y(\xi_i) \) are independent, then image will consist of random noise.
- If \( Y(\xi_i) \) are somehow related, then there will be spatial structure in the scene.
History of TRV

Developed independently in at least three fields:
- Geology: Kriging, Matheron - classic work
- Meteorology: Gandin, Matern - "objective analysis"
- Geophysics: Gratacard, Morwitz - "colocational theory"

Geologic applications -- especially in mining industry, as concentrations of minerals in ores.
- Provide minimum variance estimators of concentration at arbitrary locations (Kriging).
- Locate position of drill samples that will most effectively reduce estimate variances.
- Estimate weighted average or mean value within a region with minimum variance.
- Estimate a drift or linear trend.
Simplest Assumption: Intrinsic Hypothesis

- Deal with difference in two values as a function of spatial increment $h$:

$$Y(x+h) - Y(x)$$

- Assume first moment is constant or only slowly varying w/ $x$. I.e.,

$$E[Y(x+h) - Y(x)] = \text{constant}$$

- Then second moment is:

$$2\gamma(h) = E[(Y(x+h) - Y(x))^2]$$

$2\gamma(h)$ is termed variogram;
$\gamma(h)$ is termed semivariogram.
**Spatial Autocorrelation in TRV**

- Assume $E[Y(x)]$ is stationary in $x$.

$$m = E[Y(x_i)] = E[Y(x_j)]$$

for two locations $x_i$ and $x_j$.

- Assume covariance between $Y(x_i)$ and $Y(x_j)$ is a function only of distance $d$ between $x_i$ and $x_j$.

$$d^2 = (x_i - x_j)'(x_i - x_j)$$

Covariance = $C(d) = E[Y(x_i)Y(x_j)] - m^2$

- Correlogram - $\rho$ as a function of distance

$$\rho(d) = \frac{C(d)}{C(0)}$$

where $C(0)$ is just variance of $Y(x)$

Thus, spatial autocorrelation is easily related to TRV.

Also, power spectral density function is Fourier transform of spatial autocorrelation function $\rightarrow$ Fourier domain.

VARIogram of Agriculture Scene

one pixel = 0.15 m
Main Thrust of Work

Apply TRV to development & utilization of remote sensing models.

- Formalize relationship between variogram, correlogram, resolution, local variance, image texture for various scene models

- Investigate invertibility -- deriving parameters of elements & their distributions from the variograms

- Consider multiple spatial structures - e.g., plant → row → field → agricultural region
Primary Tasks, Yr 1

1. Application of TRV to RS scenes (Strahler, Woodcock, Hunter)
   - Examine RS scenes, determine variograms empirically.
   - Forests, agricultural scenes, housing developments, urban areas, etc.
   - Explore effects of resolution on inference on image texture.
   - Scan photos; TM & MSS imagery.
   - Construct simple scene models & generate variograms for them.

2. Formalize relation between variogram, image texture & scene model (Tobler, UCSB)
   - Examine math. relationship between variogram & image texture measures.
   - Explore conventional texture measures in context of TRV & scene model.
3) Other possible topics
   - Generalize theory of regionalized variables to multidimensional case for application to remote sensing (UCSB).
   - Use of point process models for locating objects in scenes & the variograms that such point processes imply (Hunt).  
   - Possible use of alternate geographic models -- diffusion, gravity (Hunt).  
   - Use of TRV to interpolate missing measurements due to clouds, scanner or transmission-related problems (UCSB).
### Phase I: Empirical Characterization of Spatial Patterns in RS data

APPROACHES TO IMAGE REGISTRATION AND SEGMENTATION

Grahame Smith
Image-to-Image Correspondence

different viewing conditions

different resolutions, spectral responses

temporal changes

Approach

• Detect easily recognized / physically meaningful structures

• Label structures

• Build description of structure

• Match descriptions - rough camera model

• Select feature points

• Predict how the feature points appear in image

• Match feature points - precise transform
Image Segmentation

recover scene entities
- single land cover class
- no internal boundaries

• Recover surface shape

• Initial classification

• Edge / Linear structure detection

• 'Convergence of Evidence' decision making
Detection of Linear Structures

two-fold purpose: image registration and class boundary detection

Algorithm

Peak and trough method

Finds ridge lines (skeleton)

Uses local and global nature of intensity peak
Initial Segmentation

- based on the reflectance

• little human intervention

• use catalog of reflectance versus land cover

• delineate single land cover area rather than identify class

Atmospheric Model \( I = R + S \)

Film Model \( D = a \times \ln(I) + d \)

Isotropic Scattering \( R = EAN \)

\[ D = a \times \ln(A + b) + c \]
Surface Shape Recovery

- slant of ground plane
- surface shape

\[ I(x, y) = R(l, m) \]
- type of scattering
- position and strength of light source
- surface albedo
- boundary conditions
\[
\frac{1 - m^2}{lm} = \frac{I_{xx}}{I_{xy}}
\]

\[
\frac{1 - l^2}{lm} = \frac{I_{xx}}{I_{xy}}
\]
Physical Models needed to interpret image

- Linear feature finder
- Image classification
- Shape recovery

Physical models not all encompassing

- Evidential Reasoning
Primary Areas of Focus

- Image-to-Image Correspondence
  - registration of multiple data sources
- Image Segmentation - context:land-use
  - scene entities
- 'Convergence of Evidence' Decision Making
  - multi-source integration

Approach

- Physical Modeling
- Generic Techniques based on Stable Properties
- Discover Stable Attributes
Reduction and Utilization of Speckle Noise in SAR Imagery

Daniel Held
Jet Propulsion Lab
\[ H(\omega) = \frac{\hat{S}(\omega)}{\hat{S}(\omega) + N(\omega)} \]

\[ \hat{S}(\omega) = |\text{FFT } I|^2 - \frac{1}{2} |\text{FFT } I|^2 \]

\[ \hat{S}(\omega) - N(\omega) = |\text{FFT } I|^2 \]

Progress in the Scene-to-Map Registration Task

David D. Dow
National Space Technology Labs
RTOP: SCENE-TO-MAP REGISTRATION COMPARISON FOR LANDSAT MSS AND THEMATIC MAPPER DATA

PRINCIPAL INVESTIGATOR: DAVID D. DOW

PROJECT DURATION: FY1981 - FY1984

FUNDAMENTAL RESEARCH AREA: MATHEMATICAL PATTERN RECOGNITION-GEOMETRIC PREPROCESSING
OBJECTIVE: ASSESSMENT OF GEOMETRIC ACCURACY OF SCENE-TO-MAP REGISTRATION OF LANDSAT MSS AND TM SENSOR PRODUCTS. DEVELOPMENT OF IMPROVED PROCEDURES FOR THE REGISTRATION AND RECTIFICATION OF LANDSAT DATA.

TEST LOCATIONS: SOUTHEASTERN LOUISIANA AND EASTERN KANSAS

POTENTIAL APPLICATIONS:

(1) COMPONENT OF MULTISOURCE DATA BASE
(2) DEVELOPMENT OF A CHANGE DETECTION PRODUCT
(3) INPUT TO HABITAT CLASSIFICATION
TECHNICAL QUESTIONS ADDRESSED:

1. GEOMETRIC FIDELITY OF P-FORMAT LANDSAT MSS AND LANDSAT D TM DATA.

2. INFLUENCE OF PRODUCT SCALE ON THE GEOMETRIC ACCURACY OBTAINABLE WITH CURRENT REMAPPING TECHNIQUES AND RESAMPLING FUNCTIONS.

3. ROLE OF GROUND CONTROL POINT SELECTION PROCEDURES ON DIMINISHING SPATIAL DISTORTIONS IN A-FORMAT LANDSAT MSS DATA.

4. GEOMETRIC ERRORS INTRODUCED BY CONVERSION BETWEEN BASE MAP PROJECTIONS (UTM, HOM, AND SOM).
COMPARISON OF CONTROL POINTS ON UTM GRID, UNCORRECTED LANDSAT DATA, AND GEO-REFERENCED LANDSAT DATA

(A) HYPOTHETICAL GROUND CONTROL POINTS ON UTM GRID

(B) SAME POINTS ON UNCORRECTED LANDSAT DATA (NOTE THE DIFFERENT ORIENTATION)

(C) SAME POINTS ON GEO-REFERENCED LANDSAT DATA
Where mapping function relates

\[(E,S) = Ts \circ Tp \circ Tc \ (e,s) = T(e,s)\]

and \(Ts\), \(Tp\) and \(Tc\) are vector functions

**GEOMETRIC REGISTRATION PROCESS AND ITS APPLICATIONS**
Figure 1. DISTRIBUTION OF 12 LANDSAT SCENES ACCORDING TO PATH AND ROW NUMBERS
SCENE-TO-MAP REGISTRATION

ASSESSMENT OF GEOMETRIC ACCURACY OF SCENE-TO-MAP REGISTRATION OF LANDSAT P-FORMAT MSS DATA

P-FORMAT DATA - CONTAINS RADIOMETRIC AND GEOMETRIC CORRECTIONS
\[
\text{RBIAS} = \frac{\sum_{i=1}^{NP} (ROW_{1,i} - ROW_{2,i})}{NP}
\]

\[
\text{RSD} = \sqrt{\frac{\sum_{i=1}^{NP} (ROW_{1,i} - ROW_{2,i} - RBIAS)^2}{NP-1}}
\]
INDEPENDENTLY CHOSEN CONTROL POINTS (LATITUDE, LONGITUDE, ROW2, COL2) COMPARED WITH LANDSAT COORDINATES (ROW1, COL1) DETERMINED FROM P-FORMAT REGISTRATION FOR DATA SET 1

FUNDAMENTAL RESEARCH DATA BASE

At the request of Dr. R. P. Heydorn, a fundamental research data base has been created on a single 9-track 1600 BPI tape containing ground truth, image, and Badhwar profile feature data for 17 North Dakota, South Dakota, and Minnesota agricultural sites. Each site is 5x6 nm in area. Image data has been provided for a minimum of four acquisition dates for each site. All four images have been registered to one another. A list of the order of the files on tape and the dates of acquisition is provided in attachment 1.

Attachment 2 provides information on the format of the ground truth tape and a table for each year to use in interpreting the information on the ground truth tape. Ground truth codes vary depending on the year. Like the Landsat image files, ground truth files cover an image 196 pixels wide by 117 lines long, but the actual size of the ground truth image is 392 pixels by 234 lines. The reason for this difference is that there are six ground truth subpixels for each Landsat pixel, as illustrated.

```
+---+---+---+---+---+
| C1| C2| C3| C4| C5| C6 |
+---+---+---+---+---+
       |     |     |
Landsat Pixel    Ground Truth Pixel
```

The symbols $C_1$, $C_2$, $C_3$, $C_4$, $C_5$ and $C_6$ represent the ground truth crop code for the various sub-parts of the Landsat pixel. We typically use a plurality rule to decide on a single label for a Landsat pixel.

All files are stored on tape in universal format. Image files and Badhwar profile feature files contain four channels of data, but since three Badhwar profile features are provided in the feature files ($t_D$, $\sigma$, and $G_{max}$) the fourth channel is always zero. The format for image and profile files is the same and is provided in attachment 3.

Two end-of-files
3.2.1 HEADER RECORD

The Header Record is the first record on the tape and contains 3060 bytes (8 bits per byte). The record is zero filled except for those bytes listed in the following table. The values contained in the listed bytes are all constant except for bytes 61 through 63. The attached tape format contains identification and descriptions for each byte. The description and format of the Header Record is contained in attachment 3.

</tbody>
</table>

Each video scan line is 504 bytes long; a 2-byte record counter, a 70-byte ancillary block, and 392 bytes of ground truth (two of the six subpixels for a 196 pixel scan line). It takes three video scan lines to complete one scan line of ground truth. See the following page for diagram.
Each video block will be the same number of bytes in length. If this tape contains raw data the FCM sync words associated with the video data, if any, will be included, with the video data on this tape. If this tape contains processed data, no sync words will be present.

The arrangement of data for each pixel is shown in the following diagram. Data for subpixels 1 and 2 for pixel 1 is found in bytes 73 and 74 of the first data record. Data record 2 and 3 contain data for suppixel 3 through 6 in the same format as record 1.

<td>Fill zeros, makes the record an integral number of computer words. These bytes must never contain data.</td>
</tr>
</tbody>
</table>
3.2.2 DATA SETS

The data follows the Header Record and is arranged in data sets. A data set is defined as the ancillary data and all of the video data for one scan line for all active channels. Data sets are recorded in variable length physical records containing a maximum of 3000 bytes of information per record. Since 3000 bytes is not compatible with the word length of all computers, the record includes a sufficient number of fill zero to make the record divisible by 32, 36, 48, and 60 bits. However, the maximum length of the record may not exceed 3060 bytes. If two are more records are needed for the data set, the data set will be divided. Under no condition will the data for a video channel begin in one record and continue into another record.

The first two bytes of each record will contain the number of the physical record within the video data set. This is for use in data sets that contain more than 3000 bytes and therefore require more than one physical record for recording. The ancillary block is the first block of a data set and follows the record counter. The length of the ancillary block is variable, with the number of bytes given in the header record.

Bytes 73 through N will be dependent on whether this job contains raw processed data (Byte 89 of the header record). The value of N will be given in bytes 105 and 106 of the header record and will always be greater than or equal to 70.

If this job contains raw data bytes 73 through N will contain the housekeeping data channel from the sensor, if one is available.

Following the ancillary data in each data set will be the video data for the one channel for one scan. The video data for the channel for one scan will comprise a video block.
