Numerical Simulation of Vortex Breakdown by the Vortex-Filament Method

Y. Nakamura,  
A. Leonard,  
P. R. Spalart, Ames Research Center, Moffett Field, California
The vortex-filament method was developed by Leonard (Ref. 13) and successfully applied to the wake-vortex interaction problem behind large jet aircraft (e.g., B-747) and to the spot-like disturbance in a laminar boundary layer. This method seems well suited to the simulation of vortex breakdown, in that complex systems of vortices with or without axial velocity distribution and, for example, should be capable of simulating in detail the merging process of aircraft wake vortices.

Although this report is concerned with the simulation of vortex breakdown, the method used can treat any system of vortices with or without axial velocity distribution and, for example, should be capable of simulating in detail the merging process of aircraft wake vortices.
by the space curves \([\mathbf{r}_i(\xi, t), i = 1, 2, \ldots, L]\), where \(\xi\) is a parameter along the curve and \(L\) is the number of the vortex filaments. The vortex-filament method does not have a singular vorticity distribution inside the vortex filament as does the classical point-vortex method.

The dynamics of these filaments, consistent with the theorems of Helmholtz and Kelvin, is given by

\[
\frac{d\mathbf{r}_i(c, t)}{dt} = -\sum_{j \neq i} \frac{1}{4\pi} \int [\frac{(\mathbf{r}_i - \mathbf{r}_j) \times (\partial \mathbf{r}_j / \partial \mathbf{c}) \cdot s(\mathbf{r}_i - \mathbf{r}_j, c_i, c_j)}{|\mathbf{r}_i - \mathbf{r}_j|^3}] \, dc' 
\]

(1)

The "s" function included in this equation is related to the vorticity distribution inside a vortex filament. Leonard (Ref. 13) gave two particular choices of the function "s." In this paper we use the so-called "scheme C," which is of the form

\[
s(\mathbf{r}_i, c_i, c_j) = \frac{1}{[1 + \alpha (c_i^2 + c_j^2)/2]^\beta}
\]

(2)

where the choice \(\alpha = 0.413\) for a Gaussian distribution of vorticity within the core yields the correct speed of a single vortex ring.

In vortex-flow simulations, the following two flow representations are possible:

1. Single filament to represent each physical vortex
2. Multiple filaments to represent each physical vortex

The first method was used for test problems which are not described here. These are the interaction of four vortex rings and the interaction of two pairs of wake vortices that cross at a right angle with some clearance. The results were successful and convincing. In particular, the first case produced results very close to those of experiment (Ref. 15). These preliminary results were encouraging for the application of this method to vortex breakdown. However, the single-filament representation is appropriate only when the internal structure is not of major importance. The multiple-filaments representation has to be considered when the internal structure, including axial flow, has a significant effect on the dynamics. In this paper we use the latter representation to simulate vortex breakdown. If this method proves successful and if a detailed procedure is established, many new applications to practical flows dominated by vortices may be attempted.

3. ACCURACY CHECK OF THE VORTEX-FILAMENT METHOD

We first performed an accuracy check for the three-dimensional vortex-filament method. A flow with a simple analytical expression was chosen, and its vorticity was represented by vortex filaments. Then the velocity field induced by the filaments was compared with the idealized field. This method has two numerical parameters: the core radius and the initial spacing between the vortex filaments. The accuracy is expected to improve when the number of the filaments used is increased, which makes the average distance between neighboring vortex filaments smaller. It is also interesting to estimate the relation between the optimum core radius and the average distance. We did a similar study in two dimensions, with Gaussian cores (see Ref. 16). The results suggested the relation \(\phi = 0.47\), where \(\phi\) is the core radius and \(\phi\) is the average distance. This means that the core radius should tend to zero more slowly than the average distance does.

For the test, it is convenient to choose a flow in which the vorticity sharply declines with the distance from the axis. The following expressions, often used for unbounded swirling flow, satisfy these requirements:

\[
\begin{align*}
V_x &= a_1 + a_2 \exp(-a_3 r^2) \\
V_\theta &= r_0 [1 - \exp(-b_1 r^2)]/r \\
V_r &= 0
\end{align*}
\]

(3)-(5)

where \(V_x\) is the axial-velocity component, \(V_\theta\) the theta velocity, and \(V_r\) the radial velocity. The values actually used for the parameters are

\[
\begin{align*}
a_1 &= 0.95, \quad a_2 = 1.55, \quad a_3 = 10, \quad b_1 = 10.9, \quad \text{and} \quad r_0 = 0.825
\end{align*}
\]

which approximate those obtained in an experiment inside a pipe (private communication, Uchida et al., Nagoya Univ.), as shown in Fig. 1. We are not concerned with the wall region where, of course, the idealized velocity does not match the experimental velocity because we are simulating an unbounded flow. The measurements were obtained by a laser Doppler velocimeter for axisymmetric vortex breakdown at a Reynolds number of 2300. Figure 1a shows the axial velocity component of Eq. (3) which is high near the axis and approaches 0.95 (potential flow) as the radius increases. Needless to say, this profile includes the axial flow inside the vortex. Figure 1b shows the theta velocity, with almost rigid rotation near the axis and a maximum value at \(r = 0.34\). Beyond this point the profile becomes proportional to \(1/r\) and represents a potential swirling flow for larger values of the radius. Figure 2 shows the theta-vorticity distribution, which was calculated from the axial velocity by the relation \(\psi_\theta = dV_x/dr\). Figure 3 shows the axial-vorticity distribution, which was calculated from the theta velocity by the expression \(\psi_x = dV_\theta/dr\). Figure 4 shows the distribution of the circulation, which is calculated by the expression
This has a familiar pattern of positive curvature near the x-axis approaching a constant value at infinity. Figure 5 shows the magnitude of the vorticity vector as a function of r. The deflection angle of the vorticity from the x-axis is also shown (dashed line); it increases monotonically with radius. Figure 6 shows a three-dimensional picture of the vorticity vector along the radial direction. It can be seen that the vorticity maintains a moderate deflection angle for all radii.

We now discuss the problem of discretizing the idealized vorticity field with helical vortex filaments. The circulation and helicity of each filament as well as their distribution in space must be chosen to represent the idealized vorticity field as well as possible. We divided the circular cross section radially into a number of zones or rings. Each radial zone in turn contains a number of filaments distributed uniformly in the azimuthal direction. In the present simulation we used more filaments per unit area near r = 0 where the vorticity is maximum. Using a nonuniform radial distribution of filaments allowed us to obtain a more accurate representation of the idealized flow.

First, we discuss the method used to obtain the filament circulations. For simplicity of analysis, we assume infinite, straight vortex filaments with axes in the x-direction, distributed continuously along the circumference of each ring at the radii r_i. We have the following expression for the axial vorticity produced by one of these cylindrical shells of vorticity

\[ \omega_{x1} = \Gamma_{x1} \int_{0}^{2\pi} \gamma r_i \, d\theta \, dr \]  

where \( \Gamma_{x1} \) is the circulation per unit circumference, and \( \gamma \) is the distribution function of vorticity inside a filament which is calculated from Eq. (2) as follows:

\[ \gamma(y) = \frac{ds}{dy}/4\pi y^2 = \frac{3a\omega^2/4\pi}{(y^2 + a\omega^2)^{3/2}} \]  

Equation (7) with substitution of Eq. (8) may be integrated analytically to obtain

\[ \omega_{x1} = \Gamma_{x1} \frac{2a\omega^2 r_i (r_i^2 + a^2)}{[(r_i^2 + r_i^2 + a\omega^2)]^{3/2}} \]  

We determine the optimum circulation distribution \( \Gamma_{x1} \) for given axial vorticity distribution by minimizing the square error with the total circulation fixed. This leads to the following expression for the \( H \) function

\[ H = \int_{r_i}^{\infty} \left( \omega_x - \sum_{i=1}^{N} \Gamma_{x1} \right)^2 \, dr + \lambda \left( \sum_{i=1}^{N} 2\pi r_i \Gamma_{x1} - C \right) \]  

where \( C \) is the total circulation. Differentiating \( H \) with respect to the \( \Gamma_{x1} \) and \( \lambda \) yields the following simultaneous equations for \( \Gamma_{x1} \):

\[ 2 \sum_{i=1}^{N} \int_{r_i}^{\infty} \omega_{xk}(r) \, dr \Gamma_{x1} + \lambda 2\pi r_i k = 2 \int_{r_i}^{\infty} \omega_{xk}(r) \, dr, \quad k = 1, 2, \ldots, N \]  

Solving Eqs. (11), we obtain the optimum circulation distribution \( \Gamma_{x1} \) for each ring. If \( N_i \) is the number of filaments placed in the \( i \)th ring then the circulation of each of these filaments is given by

\[ \Gamma_j = \frac{2\pi r_i \Gamma_{x1}}{N_i} \]  

The next step is to determine the angle each helical filament makes with the x-axis, the deviation angle. For this purpose we assume that the theta component of vorticity is distributed continuously and uniformly along the x-direction with \( \Gamma_{x1} \) circulation per unit axial length for the \( i \)th ring. Again, using Eq. (8) we find that the \( i \)th ring of distributed theta vorticity contributes to the theta vorticity component as follows

\[ \omega_{01} = \Gamma_{01} \frac{4\pi r_i^2 a\omega^2}{[(r_i^2 + r_i^2 + a\omega^2)]^{3/2}} \]  

The same minimization procedure used above was used to determine the optimum \( \Gamma_{01} \) except that total vorticity constraint is not imposed in this case. Finally the deviation angle from the x-axis of each filament in ring \( i \) was determined by

\[ \tan \alpha_j = \frac{\Gamma_{01}}{\Gamma_{x1}} \]
By using the circulations and deviation angles for each ring, we calculated the induced velocity at a cross section using the following expressions:

\[
\begin{align*}
V_x &= -\left(\frac{1}{4\pi}\right) \sum_{j=1}^{r} \int_{\infty}^{r_j} a_j \rho_j \left[ r \sin(a_j x') + \tilde{\theta}_j \right] - R_j \right) / F \ dx', \\
V_y &= \sum_{j=1}^{r} \left( V_y^j \sin \tilde{\theta}_j - V_z^j \cos \tilde{\theta}_j \right), \\
V_z &= \sum_{j=1}^{r} \left( V_y^j \cos \tilde{\theta}_j + V_z^j \sin \tilde{\theta}_j \right)
\end{align*}
\] (15)

where

\[ F = \left[ x'^2 - 2yR_j \cos(a_j x') - 2zR_j \sin(a_j x') + a_j^2 + r_j^2 \right]^{3/2} \]

\[
\begin{align*}
V_y &= -\left(\frac{1}{4\pi}\right) \sum_{j=1}^{r} \left[ z \sin \tilde{\theta}_j - y \cos \tilde{\theta}_j - R_j \sin(a_j x') + a_j R_j x' \cos(a_j x') \right] / F \ dx', \\
V_z &= -\left(\frac{1}{4\pi}\right) \sum_{j=1}^{r} \left[ -y \sin \tilde{\theta}_j - z \cos \tilde{\theta}_j + R_j \cos(a_j x') + a_j R_j x' \sin(a_j x') \right] / F \ dx', \\
\rho_j &= 2\pi/\lambda_j, \quad \tilde{\theta}_j = \theta_j - \theta
\end{align*}
\]

\((r_j, \tilde{\theta}_j)\) and \((r, \theta)\) are the coordinates of the filament and the point where the induced velocity is required, respectively, and \(\rho_j\) is the filament pitch. These expressions are obtained by transforming the original expressions of the induced velocities, written in the Cartesian coordinates, using the relations representing the spiral shape of the filaments.

As our first test of our discretized vorticity field we calculated the distribution of the induced, unperturbed axial and theta velocity components of the upstream flow, which for the test extended over the entire x-axis. The actual integration was performed numerically from -10 to 10 using Simpson's rule with a spacing of 0.04 for \(x\). Four rings were used radially with radii at 0.06, 0.18, 0.30, and 0.42 with 6, 6, 8, and 8 filaments in the respective rings. The core radius \(a\) of each filament was 0.16. The results along the \(z\)-axis are depicted in Fig. 7 and show very good agreement. To check for uniformity in the azimuthal direction we obtained contour plots of the induced velocity field in a plane normal to the \(x\)-axis. These are shown in Fig. 8 along with corresponding contours of the idealized field. Generally we obtained a very good representation of the idealized field with a tendency to slightly underestimate idealized values.

4. SIMULATION OF VORTEX BREAKDOWN

For conditions upstream of vortex breakdown we assumed the idealized flow from above and therefore we used the filament parameters determined above. There might be some dispute over the difference between the experimental flow inside the pipe and the unbounded flow assumed for the simulation. As mentioned above, stable vortex breakdowns are produced inside the pipe with a divergent wall or without. Although some differences might exist between the two configurations, we assume the essential ingredients remain for vortex breakdown in unbounded flow. Experimentally, vortex breakdown is easily observed in a pipe at moderate Reynolds number which makes quantitative measurements less difficult.

In its present form the vortex filament method does not explicitly include the effect of viscous diffusion. Therefore, we cannot say anything about the effect of Reynolds number on the breakdown process itself. We assume this process to be dominated by nonlinear inviscid effects. However, the upstream profiles within the vortex depend on Reynolds number as well as the vane angles which control the amount of swirling. However, by shaping the vortex filaments upstream of breakdown we can reproduce any desired velocity (and hence vorticity) profiles. In this sense we can follow changes in Reynolds number, and in the present simulation we attempt to simulate a vortex breakdown occurring at an experimental \(Re = 2300\).

For numerical purposes, we divided the flow domain into four axial subregions (Fig. 9). For simplicity just one filament is shown. Regions I, II, and IV have predetermined filament geometries. Only in region III is the flow simulated fully. Regions I, II, and IV are constructed to provide high-quality boundary data for region III. Regions I and IV consist of straight, semi-infinite filaments that induce a swirl component on the filaments in region III. Here, analytical expressions were used for the induced velocity. For example, if one of these semi-infinite filaments, parallel to the \(x\)-axis, extends from \((x_0, y_0, z_0)\) to minus infinity, the analytical induced velocity is as follows:

\[
\begin{align*}
V_x &= 0, \\
V_y &= -(r/4\pi)(z - z_0)/F, \\
V_z &= (r/4\pi)(y - y_0)/F
\end{align*}
\] (16)
with some contraction upstream. At later times the outermost filaments establish a wavy pattern downstream near the downstream boundary. Experimentally it is very often observed that axisymmetric vortex breakdown and enlargement of a low-velocity region upstream of the high-velocity region. Meanwhile, the peak velocity confined to the downstream end of the computational domain.

In Case II we added a three-dimensional perturbation to the initial disturbance as shown in Fig. 10b (t = 0). The perturbation was caused by adding a radial displacement to each filament which was a sinusoidal function of theta (wavenumber = 1) and was nonzero and sinusoidal in x for 3 < x < 4. It can be seen that differences in the filament configurations between Case I and Case II persist in time but remain confined to the downstream end of the computational domain.

A Runge-Kutta fourth-order scheme was used for time-integration. Special attention was given to the filaments of region II. Because the Runge-Kutta scheme requires four different substeps to obtain the final solution at each time-step, we must use three different geometries other than the "exact geometry" to simulate precisely the Runge-Kutta errors that are being made in the upstream part of region III. Both the radius and phase angle were precalculated for each substep and stored in the program.

At each time-step node points were redistributed and, if necessary, added to each filament to maintain a nearly constant distance between points. This was accomplished by using a parametric spline fit to obtain the space curve defining a given filament.

At present we have insufficient knowledge about the initial disturbance necessary to produce vortex breakdown. Each type of vortex breakdown might need a different initial perturbation. At least it might be natural to consider that the three-dimensional type breakdown will need a three-dimensional disturbance. Preliminary axisymmetric calculations showed that a small amplitude disturbance on a vortex with no axial flow resulted only in weak traveling waves, but a large amplitude disturbance causes breakdown similar in appearance to wave-breaking. Experimentally, vortex breakdown is sometimes very sensitive to a disturbance in that a change in breakdown pattern occurs even if the same upstream conditions are maintained. In this report we present results for two initial disturbances. Case I had an axisymmetric disturbance and Case II had a three-dimensional disturbance.

The top function (t = 0) in Fig. 10a shows the initial geometry of the vortex filaments used for Case I and represents a large amplitude disturbance. The region of full simulation (region III) extends over the range 0 < x < 5. In 0 < x < 3, the helical geometry of the upstream flow was used, but in 3 < x < 4, the helices gradually reverse pitch and the pitch was elongated by a factor of 1.4 in this decelerating region.

During the first few time-steps, a remarkable vortex swelling can be seen in the downstream region where the initial disturbance had a flow reversal (t = 1). This swelling moves downstream (t = 2). At later times these vortex filaments are elongated in the axial direction and in particular the filaments in the third ring appear almost parallel to the x-axis (t = 2 and t = 3). Just downstream of this region a narrow region with small pitch can be observed (t = 4). A central region which appears devoid of filaments due to the elongation and straightening of the filaments can also be seen at t = 6 in the middle of the picture. This region moves upstream and is a manifestation of the axisymmetric vortex breakdown. On the other hand, at t = 4 the filaments in the second and third rings show disorder just downstream of the center of the picture, followed by a contraction toward the x-axis near the downstream boundary. In contrast with this, the filaments in the innermost ring show slight expansion near the downstream boundary with some contraction upstream. At later times the outermost filaments establish a wavy pattern downstream of the first expansion. At t = 6 most filaments have become very disordered near the downstream boundary. Just upstream of this expansion the filaments of the second and third rings have become "untied" and elongated in the axial direction. Another interesting feature is that the filaments in the innermost ring contract to r = 0 at the station where the outer filaments show the expansion at t = 2. This region of contraction has a long axial extent by t = 3 and then moves downstream with time.

In Case II we added a three-dimensional perturbation to the initial disturbance as shown in Fig. 10b (t = 0). The perturbation was caused by adding a radial displacement to each filament which was a sinusoidal function of theta (wavenumber = 1) and was nonzero and sinusoidal in x for 3 < x < 4. It can be seen that differences in the filament configurations between Case I and Case II persist in time but remain confined to the downstream end of the computational domain.

Figure 11 shows the contours of axial velocity. Solid lines denote positive values and dashed lines negative values. Figure 11a shows Case I. Initially (t = 0), a downstream region of low axial velocity is shown as expected from the initial geometry of the filaments. By t = 1 this low-velocity region has gone through the downstream boundary and cannot be seen. Instead a high-velocity region appears. Between t = 1 and t = 2 this high-velocity region enlarges and moves downstream. At later times we see the development and enlargement of a low-velocity region upstream of the high-velocity region. Meanwhile, the peak velocity in the high-speed region is decreasing. At t = 7 and t = 8 we see another interesting feature. Near the downstream boundary another low-velocity region appears. Apparently, a second breakdown is occurring near the downstream boundary. Experimentally it is very often observed that axisymmetric vortex breakdown is followed by a second breakdown of the spiral type. In the experiment used to determine the upstream conditions a clear spiral-type vortex breakdown was observed. However, the axisymmetric initial disturbance for Case I only leads to axisymmetric flow.
Next, we discuss Case II (Fig. 11b), having a three-dimensional initial disturbance. Generally, Case II shows a pattern similar to that of Case I. However, we again see that three-dimensionality remains at later times, but only near the downstream boundary. As seen at t = 5 and later, the contours in the first breakdown are very similar to those in Case I and appear axisymmetric. But the second breakdown is distorted, not axisymmetric, and appears to be rotating around the x-axis (as seen in the downstream region at t = 7 and 8). This is suggestive of a vortex breakdown of the spiral type.

Figure 12 shows the theta velocity contours. For Case I at t = 0, the contours show no disturbance in the theta velocity because the filaments are distorted initially only in the theta direction. At t = 1, swelling of contour lines can be seen in the region of the initial perturbation. At t = 2 an interesting phenomenon appears downstream. Another swelling after the first swelling can be seen near the downstream boundary. At this time the swelling of the filaments near the x-axis seen at t = 1 has disappeared. The contours at t = 3 are similar to those at t = 2. Between t = 2 and t = 4 the axial position of the maximum swelling of the level 3 contour clearly moves upstream. After t = 6 the first swelling spreads to the contours near the x-axis. The first and the second swellings correspond to the two breakdowns observed above.

For Case II (Fig. 12b) we see that at t = 0 the contour lines have a slightly crooked pattern for 3 < x < 4 where the initial three-dimensional disturbance was imposed. At t = 1 we can see the clear three-dimensional wavy pattern inside the region of swelling. At t = 2 the three-dimensionality moves toward the downstream boundary and seems to disappear until t = 7. At t = 7 and t = 8 we clearly observe three-dimensionality near the downstream boundary and a comparison of the contours at these two times indicates a rotating disturbance. This is in contrast with the first breakdown whose contours appear to be nearly axisymmetric and agree well with those of Case I. We conclude that the complete pattern of an axisymmetric vortex breakdown followed by a breakdown of the spiral type was simulated by allowing for three-dimensionality.

5. CONCLUDING REMARKS

The vortex-filament method was applied to the numerical simulation of vortex breakdown, which is intrinsic to the longitudinal vortex. Generally, there are three types of vortex breakdown: axisymmetric, spiral, and double helix. In this paper we simulated the axisymmetric type of vortex breakdown. Generally, it is difficult to obtain information experimentally due to the sensitivity of breakdown to any perturbation. Calculated results should be helpful to understand this complicated phenomenon. The principal vortex region was represented by the multiple filaments. One filament is not enough to represent this complicated flow field. In particular, the present method can include axial flow which is often observed in physical vortices.

Vortex breakdown was simulated under the assumption of nonlinear, inviscid dynamics of vorticity using the three-dimensional vortex-filament method. Viscous effects are assumed to be important only in forming upstream velocity profiles. Upstream profiles were simulated accurately with helical vortex filaments by choosing pitch and circulation to minimize the error. First, an accuracy check was performed for a cylindrical flow with simple analytical functions for the axial and theta velocities. This profile was the idealization for the experimental data used for the vortex-breakdown simulation. Comparison of the simulated results with the idealized flow suggests that the flow field can be simulated to any accuracy by increasing the number of the filaments.

Two cases, Case I and Case II, were calculated to simulate axisymmetric-type breakdown. In order to create a strong initial disturbance, the filaments in the downstream axial region were provided with a change in pitch. We used two kinds of initial disturbance to see their effect on vortex breakdown. Case I had an axisymmetric disturbance and Case II had a three-dimensional disturbance. Filament configurations and contour plots of velocity showed, for both cases, two simultaneous vortex breakdowns. One vortex breakdown was similar in both cases and was axisymmetric. The other vortex breakdown was axisymmetric for axisymmetric disturbances and three dimensional for three-dimensional disturbances. The latter case agrees with the experimental observations where an axisymmetric vortex breakdown is followed by a spiral-type breakdown.

Other types of breakdown (spiral and double-helix) should be possible to simulate by this method. The present method can also be applied to other vortex flows with axial velocity profile.

Fig. 12. Theta velocity contours. (a) Case I; (b) Case II.
The vortex-filament method was applied to the simulation of vortex breakdown. The principal vortex region was represented by multiple filaments, and an axial velocity component was induced by a spiral winding of the filaments. First, an accuracy check was performed for a cylindrical swirling flow with simple analytical expressions for the axial and theta velocities. The result suggests that the flow field can be simulated to any accuracy by increasing the number of filaments. Second, an axisymmetric-type vortex breakdown was simulated, with experimental data serving as upstream conditions. The calculated axial- and theta-velocity contours show the breakdown of the vortex, including a rapid change in the vortex core, followed axially by a recovery zone and then a second breakdown. When three-dimensional initial data are used the second breakdown appears to be of the spiral type in correspondence with experimental observations. The present method can easily be used to simulate other types of vortex breakdown or other vortex flows with axial velocity.
