INTRODUCTION

High power lasers have potential in space power transmission and spacecraft propulsion. Of the several options for the generation of laser beams in space, the direct conversion of solar radiant energy into a population inversion appears particularly attractive. Direct solar pumping for space power applications was first demonstrated in alkyliodide gases. To develop this photochemical laser system further, some attention must be given to the chemical reversibility and reprocessing requirements in scaling to large space systems.

Although the photochemical processes of alkyliodide gases have been greatly clarified in recent years, considerable uncertainty in specific rate coefficients adversely impact models used for scaling of the photodissociative 1.3-μm iodine laser system (ref. 1). Through laser kinetics, the characteristic output of an experimental laser can be related to specific rate coefficients. In this way, critical coefficients can be identified and perhaps estimated from experimental lasing of the iodine atom. The laser experiments to be analyzed in this paper were performed using n-C$_3$F$_7$I as the lasant, a high-pressure xenon arc lamp with a parabolic reflector as a solar simulator, and a MgF$_2$-coated aluminum conic collector to focus the light in the laser tube. The experimental apparatus and procedures are described in reference 2.

A preliminary model of the iodine laser kinetics (ref. 1) has shown some success in predicting the experimental laser characteristics (ref. 2), especially the lasing threshold and the early pulse structure of the laser output. The model developed in the present paper accounts for nonuniform light exposure in the laser tube and results in a reevaluation of some kinetic coefficients.

SOLAR-SIMULATOR LAMP

At the temporal peak of the solar-simulator pulse, the intensity of illumination in the region of the laser tube is

\[
C(r,\lambda) = C_o \exp\left[-2.77 \left(\frac{\lambda^2}{L^2} + \frac{r^2}{R^2}\right)\right]
\]

(1)

where \(C_o = 2.7 \text{ kW/cm}^2\), \(L = 4.75 \text{ cm}\), \(R = 0.325 \text{ cm}\), \(\lambda\) is the distance along the axis of symmetry of the lamp image, and \(r\) is the corresponding radial distance. (Symbols used in this paper are defined after the references.) Because of the relatively large magnification factors in focusing the small high-pressure arc image in the laser tube, small temporal fluctuations of the arc plasma cause large spatial movements of the image in the laser tube. This produces some difficulty in interpretation of the experiments since the instantaneous pump power in the laser tube is generally less than its maximum. Only by considering many experimental runs can the ideal experimental result be identified. The photodissociation rates of the laser
gases calculated for the line width \( D_0 \) and absorption cross section \( \sigma_0 \) at the line center \( \lambda_0 \) are

\[
\xi_i = S_i \left[ f \exp(-\sigma_0 px) + (1 - f) \exp(-0.223\sigma_0 px) \right]
\]  

(2)

where \( p \) is the alkylidene partial pressure, \( x \) is the depth of penetration, \( S_i \) is the maximum photodissociation rate, \( f \) is the fractional absorption for wavelengths near the line center, and \( (1 - f) \) is the fractional absorption in the wings. Equation (2) does not explicitly depend on line width \( D_0 \) because the line width is small compared with the spectral band of the simulator output. Values of photodissociation parameters from references 3 to 5 are given in table I. The

The effective arc temperature after reflection from the parabolic mirror was taken as 6000 K, and the reflection coefficients of the conic collector for ultraviolet \( (R_{uv}) \) and visible \( (R_{vis}) \) light are taken as those typical for MgF₂-coated aluminum surfaces.

LASER KINETICS

The basic kinetic processes for the photodissociative iodine laser are shown in figure 1 including all known chemical reactions. The kinetic equations on the center line of the 0.35-cm-radius laser tube are
\[ \frac{d[R]}{dt} = \left( \frac{R_{uv}}{R_{vis}} \right) \xi_1[R] - K_1[R][I^*] - K_2[R][I] - 2K_3[R]^2 \] (4)

\[ \frac{d[R_2]}{dt} = K_3[R]^2 \] (5)

\[ \frac{d[I_2]}{dt} = C_1[I][I^*][RI] + C_2[I]^2[RI] + C_3[I][I^*][I_2] + C_4[I]^2[I_2] - \xi_2[I_2] \] (6)

\[ \frac{d[I^*]}{dt} = \left( \frac{R_{uv}}{R_{vis}} \right) \xi_1[RI] + \xi_2[I_2] - K_1[R][I^*] - C_1[I][I^*][RI] - C_3[I][I^*][I_2] - Q_1[I^*][RI] - Q_2[I^*][I_2] - \Gamma_{max} - A[I^*] \] (7)

\[ \frac{d[I]}{dt} = \xi_2[I_2] + Q_1[I^*][RI] + Q_2[I^*][I_2] + \Gamma_{max} + A[I^*] - C_1[I][I^*][RI] - 2C_2[I]^2[RI] - C_3[I][I^*][I_2] - 2C_4[I]^2[I_2] - K_2[R][I] \] (8)

\[ \frac{dp}{dt} = \Gamma_{max} \left( \frac{\pi}{2.77} \right)^{1/2} \frac{L}{L_c} - \frac{1}{\tau_c} \rho + gA[I^*] \] (9)

\[ \Gamma_{max} = \cos \left( \frac{[I^*] - \frac{1}{2}[I]}{[I^*]} \right) \] (10)

Kinetic rate coefficients (refs. 6 to 21) are given in table II. The stimulated emission cross section (cm\(^2\)) is (ref. 13)

\[ \sigma = (2 \times 10^{17} + 0.443[RI])^{-1} \] (11)
Figure 1.-- Energy diagram of alkyl iodide photochemical laser showing kinetic pathways.

TABLE II. - MEAN KINETIC RATE COEFFICIENTS OBTAINED FROM THE LITERATURE AND THE ASSOCIATED UNCERTAINTY FACTORS

The factor in parentheses gives the uncertainty limits associated with each rate

The Einstein coefficient $A$ is 7.7 sec$^{-1}$ (according to ref. 13), and $\tau_c$, the optical cavity time constant (ref. 22), is

$$\tau_c = \frac{-2(L_c/c)}{\ln r_1 r_2}$$

where $L_c$ is the distance (56 cm) between the mirrors forming the optical cavity, $c$ is the velocity of light, $r_1$ and $r_2$ are the reflection coefficients (0.9775 and 0.9975) at the ends of the cavity including Brewster window losses, $\rho$ is the average photon density in the optical cavity, and $g$ is the coupling parameter of the spontaneous emission to the optical cavity (ref. 1):

$$g = \frac{2r_b^2}{L_c^2}$$

where $r_b$ is the laser beam width (approximately 0.18 cm) of the appropriate oscillator mode. The factor $((\pi/2.77)^{1/2}$ in equation (9) is a geometric factor resulting from nonuniform pumping and $\Gamma_{\text{max}}$ is the stimulated emission rate at the spatial peak of the pump pulse. In the above equations, the relaxation of the hyperfine states which is important in determining threshold (ref. 13) and in influencing the laser pulsations early in the laser pulse has been ignored. Special attention is now given to the quasi-CW (continuous wave) portion of the pulse for which the hyperfine relaxation times are short compared with laser pulse fluctuations. Of interest here are the kinetic processes which dominate at late times in the laser output.

After the initial laser pulsations, the photon density becomes steady as gains and losses balance each other within the cavity and gain medium, as expressed by

$$\rho = \left(\frac{\pi}{2.77}\right)^{1/2} \Gamma_{\text{max}} L \frac{\tau_c}{L_c}$$

or equivalently

$$[I*] - \frac{1}{2}[I] = -\frac{1}{2} \frac{\ln r_1 r_2}{(\pi/2.77)^{1/2}} L \sigma \equiv I_{\text{th}}$$
where \( I_{th} \) is the threshold inversion density. One may also show that under quasi-steady-state conditions,

\[
\Gamma_{\text{max}} = \left( \frac{R_{uv}}{R_{\text{vis}}} \right) \xi_1[RI] + \xi_2[I_2] - K_1[R][I^*] - Q_1[RI][I^*] \\
- Q_2[I_2][I^*]
\]  

(16)

with the laser output power density \((W/cm^2)\) given by

\[
P = -\frac{\varepsilon}{\nu} \Gamma_{\text{max}} \left( \frac{\pi}{2.77} \right)^{1/2} \frac{L_{t_m}}{\ln r_1 r_2}
\]

(17)

where \( \varepsilon_{\nu} \) is the photon energy and \( t_m \) is the output mirror transmission coefficient. From equations (16) and (17), the laser output clearly depends on the time-dependent composition of the gas and photodissociation rate.

Note that the recombination rate \( K_1[R] \) is large compared with the parent gas quenching rate \( Q_1[RI] \), and after lasing is achieved, both are small compared with the photodissociation rate of the parent gas. Early in the pump pulse, \([I_2]\) is still small so that

\[
P = -\frac{\varepsilon}{\nu} \xi_1[RI] \left( \frac{\pi}{2.77} \right)^{1/2} \frac{L_{t_m}}{\ln r_1 r_2}
\]

(18)

until late enough in the pump pulse that appreciable quenching by \( I_2 \) commences.

Results for \( n-C_3F_7I \) from equation (18) are shown in figure 2 in comparison with experiments (ref. 2). The experimental values shown are peak values of the quasi-CW portion of the pulse during several experimental runs and do not always correspond to times when the arc was properly focused. Also, the present calculations indicate that the detectors in reference 2 were saturated. The saturated detector response (fig. 3) was determined through calibration with a flash-lamp-pumped iodine laser. The data used to evaluate rate coefficients are based on the measured recalibration curve of the saturated detector response as shown in figure 3. The late-time CW pulse shape is then related to the processes forming \( I_2 \) and to the \( I_2 \) quenching coefficient.
Figure 2. - Laser output intensity (eq. (18)) as a function of alkyliodide lasant pressure in comparison with experimental values taken from reference 2.

Figure 3. - Germanium detector calibration curve for the 1.3-μm iodine laser output.
When the laser is in quasi-steady-state operation, photodissociation is balanced by recombination of the ground state \( I \) with the alkyl radical to yield approximately

\[
K_2[I][R] = \xi_1[RI] \quad (19)
\]

Since the gain medium is saturated, \([R] = \frac{3}{2}[I]\), so that

\[
[I] = \left( \frac{2\xi_1[RI]}{3K_2} \right)^{1/2} \quad (20)
\]

Using equation (20) in equation (6) and neglecting the small terms involving \( C_1 \), \( C_3 \), and \( C_4 \), since the \([RI]\) is large and \( I + I^* \) recombination is slow, yields through integration

\[
[I_2] = \frac{c_2[RI][I]^2}{\xi_2} \{1 - \exp[-\xi_2(t - t_{th})]\}
\]

\[
= \frac{c_2[RI][I]^2}{\xi_2}(t - t_{th}) \quad (21)
\]

which is applicable for times \((t)\) after threshold is achieved \((t_{th})\). Clearly from equations (20) and (21), the \( I_2 \) quenching rate is

\[
q_2 = \frac{Q_2}{K_2} \frac{c_2}{\xi_2} \xi_1[RI]^2(t - t_{th}) \quad (22)
\]

which displays the important processes leading to the temporal variation of the late-time pulse dependence. The quantity \( q_2 \) is quite uncertain as seen from the uncertainties of \( Q_2 \), \( C_2 \), and \( K_2 \) in table II. An attempt is now made to obtain new rate coefficients and uncertainty limits from the experimental laser data.

RESULTS

A laser pulse for which the arc plasma was reasonably stationary is shown in figure 4, although motion of the arc is evident after 1.6 ms. These data are used to derive an upper bound on the late-time quenching rate \( q_2 \). For the kinetic coefficients and uncertainties for \( n-C_3F_7I \) listed in table II, the rate constant factor in equation (22) satisfies

\[
1.4 \times 10^{-33} < \frac{Q_2C_2}{K_2} < 3.4 \times 10^{-30} \quad (23)
\]
However, the present kinetic model showed the mean values of table II for $Q_2$, $C_2$, and $K_2$ to result in excessive quenching. New limits on these coefficients obtained from the experiments of reference 2 are shown in table III. New limits on the quenching rate factor obtained from table III are given by

$$3.8 \times 10^{-33} < \frac{Q_2 C_2}{K_2} < 1.9 \times 10^{-31}$$

</table>
The calculated germanium detector response to the theoretical laser output for the kinetic rates $K_2 = 2.3 \times 10^{-11}$, $Q_2 = 4.4 \times 10^{-11}$, and $C_2 = 6.9 \times 10^{-32}$ is shown in figure 4 in comparison with the experimental detector response. Note that because the image of the arc was offset from the laser tube axes, only 40-percent power levels were achieved. Also shown in table III are kinetic rate coefficients associated with other experiments which are clearly inconsistent with the present results. In particular, the present value of $K_2$ lies midway between the previously reported values which differed by an order of magnitude. The earlier values of $Q_2$ (refs. 6 and 15) differ from the present results, while more recent work (refs. 8 and 16 to 19) is consistent with our results. Although the n-C$_3$F$_7$I stabilized I + I recombination coefficient found by Kuznetsova and Maslov (ref. 7) is consistent with the present value of $C_2$, much lower values cannot be ruled out by the present analysis.

</table>
The literature contains broad ranges of disagreement in kinetic data for the atomic iodine laser. A kinetic model of a solar-simulator-pumped iodine laser is used to select those kinetic data consistent with recent laser experiments at the Langley Research Center. Analysis of the solar-simulator-pumped laser experiments resulted in the following estimates of rate coefficients: for alkyl radical (n-C₃F₇) and atomic iodine (I) recombination, $4.3 \times 10^{-11} (1.9)^{\pm 1} \text{ cm}^3/\text{s}$; for n-C₃F₇ stabilized atomic iodine recombination (I + I) $3.7 \times 10^{-32} (2.3)^{\pm 1} \text{ cm}^5/\text{s}$; and for molecular iodine (I₂) quenching, $3.1 \times 10^{-11} (1.6)^{\pm 1} \text{ cm}^3/\text{s}$. These rates are consistent with the recent measurements.
