Bifurcation Analysis of Aircraft Pitching Motions Near the Stability Boundary

W. H. Hui, University of Waterloo, Waterloo, Ontario, Canada
Murray Tobak, Ames Research Center, Moffett Field, California
ABSTRACT. Bifurcation theory is used to analyze the nonlinear dynamic stability characteristics of an aircraft subject to single-degree-of-freedom pitching-motion perturbations about a large mean angle of attack. The requisite aerodynamic information in the equations of motion can be represented in a form equivalent to the response to finite-amplitude pitching oscillations about the mean angle of attack. It is shown how this information can be deduced from the case of infinitesimal-amplitude oscillations. The bifurcation theory analysis reveals that when the mean angle of attack is increased beyond a critical value at which the aerodynamic damping vanishes, new solutions representing finite-amplitude periodic motions bifurcate from the previously stable steady motion. The sign of a simple criterion, cast in terms of aerodynamic properties, determines whether the bifurcating solutions are stable (supercritical) or unstable (subcritical). For flat-plate airfoils flying at supersonic/hypersonic speed, the bifurcation is subcritical,
implying either that exchanges of stability between steady and periodic motion are accompanied by hysteresis phenomena, or that potentially large aperiodic departures from steady motion may develop.
1. INTRODUCTION. Problems of aerodynamic stability of aircraft flying at small angles of attack have been studied extensively. With increasing angles of attack the problems become more complicated and typically involve nonlinear phenomena such as coupling between modes, amplitude and frequency effects, and hysteresis. The need for investigating stability characteristics at high angles of attack was clearly demonstrated by Orlik-Rückemann [1] in his survey paper which largely deals with experiments.

On the theoretical side, the greater part of an extensive body of work is based on the linearized theory, in which the unsteady flow is regarded as a small perturbation of some known steady flow (possibly nonlinear in, e.g., the angle of attack) that prevails under certain flight conditions. The question of the validity and limitations of such a linearized perturbation theory is of fundamental importance and yet has been investigated only rarely. One may argue that in principle, it should be possible to advance to higher and higher angles of attack \( \sigma \) by a series of linear perturbations, since the solution at each step should include a steady-state part which, when added to the previous steady-state solution, would provide the starting point for the next perturbation. This may well be true provided that at each step the steady motion is stable both statically and dynamically, and that the actual disturbances, e.g., the amplitude of oscillation, remain small. However, the linear perturbation procedure must eventually cease to be valid when the angle of attack exceeds a certain critical value \( \sigma_{cr} \) at which the steady motion is no longer stable.
In this paper we investigate the stability characteristics of an aircraft trimmed to a mean angle of attack $\sigma_m$ near $\sigma_{cr}$ at which the steady motion becomes unstable. Padfield [2] studied a similar problem, using the method of multiple scales, which is valid only for weakly nonlinear oscillations. We shall study the problem by means of bifurcation theory. This will allow us to draw on recent mathematical developments (e.g., [3]) that are particularly well suited to investigating fundamental questions in linear and nonlinear stability theory. A numerical scheme based on bifurcation theory was proposed earlier [4] for analyzing aircraft dynamic stability in a rather general framework. More recent work [5] demonstrates the considerable potential of bifurcation theory in flight dynamics studies, particularly toward establishing a method for the design of flight control systems to ensure protection against loss of control. On the other hand, while acknowledging the importance of the aerodynamic model in determining the aircraft stability characteristics, neither of these works contains an adequate assessment of the model requirements. The treatment of unsteady flow effects, in particular, receives no attention. In contrast, we shall focus on just this aspect of the problem at the expense of narrowing the scope of the motion analysis. Restricting the motion to a single-degree-of-freedom pitching oscillation will enable us to analyze a motion for which complete aerodynamic information is available, for certain aerodynamic shapes, in the form of exact solutions of the inviscid supersonic/hypersonic unsteady flow theory [6-10]. In this way it will be possible to establish a form revealing a precise analytical relationship between
the basic aerodynamic coefficients and the characteristics of the motion.
For a more extensive account of the analysis presented here, see [11].

2. MATHEMATICAL FORMULATION.

A. The Coupled Dynamic/Aerodynamic System. We restrict attention
to the single-degree-of-freedom pitching oscillations of an aircraft
about a fixed trim angle. Before time zero, let the aircraft be in
level, steady flight with its longitudinal axis inclined from the hori-
zontal velocity vector by the fixed trim angle of attack $\sigma_m$. At
time zero the aircraft is perturbed from its trim position, but during
the subsequent motion the center of gravity continues to follow a recti-
linear path at constant velocity $V_\infty$. The instantaneous angle of attack
$\sigma(t)$ is again measured relative to the horizontal velocity vector, while
the inclination of $\sigma(t)$ from the fixed trim angle $\sigma_m$, $\sigma(t) - \sigma_m$, will
be designated $\xi(t)$. The equations of motion are

$$\frac{d}{dt} (\sigma - \sigma_m) = \dot{\xi}$$

(2.1a)

$$I \frac{d\dot{\xi}}{dt} = M(t)$$

(2.1b)

where $I$ is the moment of inertia and $M(t)$ the instantaneous aerody-
namic pitching moment, both referred to the center of gravity. We
assume that the moment required to trim the aircraft at $\sigma_m$ has been
accounted for, so that $M(t)$ is a measure of the perturbation moment
only.

Now we consider the equations governing the flow around the aircraft,
assuming for simplicity that it is permissible to neglect viscous effects.
The inviscid unsteady flow-field equations are
\[
\frac{\partial p}{\partial t} + \mathbf{v} \cdot (\rho \mathbf{v}) = 0 \tag{2.2a}
\]
\[
\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} + \frac{\mathbf{v} p}{\rho} = 0 \tag{2.2b}
\]
\[
\frac{\partial}{\partial t} \frac{\rho}{\gamma} + \mathbf{v} \cdot \nabla \frac{\rho}{\gamma} = 0 \tag{2.2c}
\]

where \( p, \rho, \) and \( \mathbf{v} \) are the pressure, the density, and the velocity vector, respectively, and \( \gamma \) is the ratio of specific heats of the medium. Denote the position vector originating from the center of gravity by \( \mathbf{T} \) and let the equation of the body surface be

\[ B(\mathbf{T}, \xi(t)) = 0, \]

which, as noted, depends on the instantaneous displacement angle \( \xi(t) \). The tangency condition at the body surface is then

\[
\frac{\partial B}{\partial t} + \mathbf{v} \cdot \nabla B = 0 \quad \text{on} \quad B = 0 \tag{2.3}
\]

which also depends on \( \xi(t) \). The far-field boundary conditions (relative to a coordinate system fixed in the aircraft) are

\[ p = p_\infty, \quad \rho = \rho_\infty, \quad \mathbf{v} = \mathbf{V}_\infty \tag{2.4}\]

for subsonic flight, or the well-known shock jump conditions for supersonic flight.

It is clear from the above that the pitching motion of the aircraft \( \xi(t) \) is coupled to the unsteady flow field (e.g., the pressure \( p \)) through (2.3), and, more directly, through \( M(t) \) in (2.1a,b), which is determined from the instantaneous surface pressure through

\[
\dot{M}(t) = \iint_{S: B=0} \mathbf{T} \times p \frac{\mathbf{V}B}{|\mathbf{V}B|} \, dS \tag{2.5}
\]

The principal difficulty, however, is that the instantaneous surface pressure in (2.5) depends not only on the current state of the flow.
field but also on its prior states. This means that past values of $\xi$ figure in the determination of the current state of the flow field and $\dot{M}(t)$ is a functional, not a function, of $\xi(t)$. Thus, unless approximations are introduced, a determination of $\xi$ starting from given initial conditions requires the simultaneous solution of the coupled equations (2.1-2.5).

Although the simultaneous solution of the coupled equations (2.1-2.5) in principle represents an exact approach to the problem of determining time-histories of maneuvers from given initial conditions, it is inevitably a difficult and costly approach (see the discussion of [12]). Approximate approaches leading to simpler, less costly computations are a practical necessity. To date, these computations have invoked the assumption of a slowly varying motion of known form (e.g., a harmonic motion) whose aerodynamic force and moment response at $t$ could be calculated. This stratagem, in effect, uncouples the flow-field equations from the equations of motion. In a series of papers (see in particular [13]), Tobak and Schiff have shown how this stratagem can be rationalized to create mathematical models of the aerodynamic response at various levels of approximation of the dependence on the past motion. (See also the contribution of Tobak, Chapman, and Schiff in this collection.)

B. Uncoupling Near Neutral Dynamic Stability Boundary. Let us suppose that there is a mean angle of attack $\sigma_m = \sigma_{cr}$ at which the damping-in-pitch coefficient vanishes. Then, at and beyond this angle of attack, the steady motion of the aircraft will no longer be stable
so that, in response to a disturbance, the motion will seek a new stable state which usually will consist of a finite-amplitude periodic oscillation about the mean angle of attack. The changeover from a stable steady motion to a stable periodic motion is called a Hopf bifurcation (see [3, 14], also Sec. 4). Thus, in the vicinity of $c_{cr}$, where the damping-in-pitch coefficient will be near zero, the consequent persistence of oscillatory motions will make it particularly appropriate to assume a periodic past motion about a mean position in calculating the aerodynamic pitching moment from the flow-field equations for use in (2.1). This assumption is consistent with the mathematical modeling approach of Tobak and Schiff [13] at the second level of approximation.

It will be convenient to write $M(t)$ in the form

$$M(t) = \frac{1}{2} \rho_{\infty} V_{\infty}^2 S \xi [C_m(\xi, \dot{\xi}, \sigma_m) - C_m(0,0,\sigma_m)]$$

(2.6)

The function $C_m(\xi, \dot{\xi}, \sigma_m)$ is the pitching-moment coefficient resulting from a finite-amplitude periodic pitching motion $\xi(t)$ about the center of gravity, and $C_m(0,0,\sigma_m)$ is its steady-state value at the mean angle of attack $\sigma_m$. The function $C_m(\xi, \dot{\xi}, \sigma_m)$ depends on the instantaneous displacement angle $\xi(t)$, its rate of change $\dot{\xi}(t)$, and the mean angle of attack $\sigma_m$. It also depends, of course, on the location $h$ of the center of gravity relative, say, to the wing leading edge, the flight Mach number $M_{\infty}$, the ratio of the specific heats of the medium $\gamma$, and the aircraft shape. A great amount of work has been devoted to the theoretical determination of the function $C_m$ for the case of pitching oscillations of infinitesimal amplitude. For example, for the cases of a wedge, a flat plate in supersonic/hypersonic flow [7, 8] and an airfoil
of arbitrary profile in the Newtonian limit [9], this function is available in exact analytical form for large, as well as small, mean angles of attack $\sigma_m$, and includes the critical angle $\sigma_{cr}$. On the other hand, little is known about the pitching-moment coefficient $C_m$ when the amplitude of oscillation is finite, except for the special case of a slowly oscillating wedge [10]. In the next section we shall show how the function $C_m$ for slow pitching oscillations of finite amplitude may be obtained from its behavior in the limit of oscillations of infinitesimal amplitude.

C. The Pitching-Moment Function for Slow Pitching Oscillations of Finite Amplitude. Consider a uniform flow $\vec{v}_\infty$ past an aircraft that is undergoing a slow pitching oscillation of finite amplitude about a mean angle of attack $\sigma_m$. The instantaneous angular displacement from the mean position is measured by $\xi(t)$ so that $|\xi|_{\text{max}}$ is the finite amplitude of the oscillation. It is required to calculate the unsteady pressure field, hence the form of the pitching moment $M(t)$ in (2.1).

Let the cylindrical coordinates $(r, \phi, z)$ be such that the $z$-axis coincides with the lateral axis through the center of gravity. Let the equation of the body surface at the mean angle of attack $\sigma_m$ be $\phi = \sigma_m + A(r, z)$. Then its equation at time $t$ is

$$B(r, \phi, z, t) = A(r, z) + \sigma_m + \xi(t) - \phi = 0 \quad (2.7)$$

With velocity vector $\vec{v} = (v_r, v_\phi, v_z)$, the boundary condition (2.3) becomes

$$v_\phi = r(\dot{\xi} + v_r \frac{\partial A}{\partial r} + v_z \frac{\partial A}{\partial z}) \quad (2.8)$$
at $\phi = A(r, z) + \sigma_m + \xi(t)$. Equations (2.2), (2.4), and (2.8) complete the formulation for calculating the flow field in terms of $\xi(t)$. Now, for a long-established periodic motion of the aircraft, the aerodynamic response is also periodic. Furthermore, invoking the assumption of slow oscillations allows us to neglect terms of $O(\xi^2, \dot{\xi})$ and higher and to write

$$
p = p_0 + \xi p_1, \quad \rho = \rho_0 + \xi \rho_1, \quad \dot{v} = \dot{v}_0 + \xi \dot{v}_1$$

(2.9)

where $(\cdot)_0$ and $(\cdot)_1$ are independent of $\dot{\xi}(t)$, but may depend on time through the function $\xi(t)$. Since the zeroth-order quantities $(\cdot)_0$ represent the flow field when $\dot{\xi} = 0$, such a flow must be quasi-steady; i.e., the time variable $t$ can only appear implicitly through the instantaneous displacement angle $\xi(t)$. Hence,

$$p_0 = p_0(\sigma_m + \xi(t), r, \phi, z), \text{ etc.}$$

(2.10)

To derive the mathematical problem for the first-order quantities $(\cdot)_1$, we substitute (2.9) into (2.2), (2.4), and (2.8), use (2.10), and neglect terms of $O(\xi^2, \dot{\xi})$. Thus,

$$\nabla \cdot (\rho_0 \dot{v}_1 + \rho_1 \dot{v}_0) = -\frac{\partial p_0}{\partial \xi}$$

(2.11a)

$$\dot{v}_0 \cdot \nabla v_1 + \dot{v}_1 \cdot \nabla v_0 + \frac{1}{\rho_0} \left( \nabla p_1 - \frac{\rho_1}{\rho_0} \nabla p_0 \right) = -\frac{\partial \dot{v}_0}{\partial \xi}$$

(2.11b)

$$\dot{v}_0 \cdot \nabla \frac{\rho_1 \dot{v}_0 + \rho_0 \dot{v}_1}{\rho_0} + \dot{v}_1 \cdot \nabla \frac{p_0 - \rho_0}{\rho_0} = -\frac{\partial p_0}{\partial \xi} \frac{\rho_0}{\rho_0}$$

(2.11c)
\[ \dot{V}_1 = p_1 - \rho_1 = 0 \quad \text{as} \quad |\dot{r}| \to \infty \quad (2.11d) \]

and

\[ V_1^\phi = r \left( 1 + V_1 \frac{\partial A}{\partial r} + V_1 \frac{\partial A}{\partial z} \right) \quad (2.11e) \]

at

\[ \phi = A(r,z) + \sigma_m + \xi(t) \]

Since the time variable \( t \) appears in (2.11) only as a parameter through \( \xi(t) \), the solution to (2.11) must be of the form

\[ p_1 = p_1(\sigma_m + \xi(t), r, \phi, z), \quad \text{etc.} \quad (2.12) \]

The forms of \( p_\phi \) and \( p_1 \) in (2.10) and (2.12) determine the form of the pressure \( p \) in (2.9) which, in turn, determines the form of the pitching-moment coefficient after the integrations indicated in (2.5) have been carried out. Thus

\[ C_m(\xi, \dot{\xi}, \sigma_m) = f(\sigma_m + \xi) + \frac{\xi \xi}{V_\infty} g(\sigma_m + \xi) \quad (2.13a) \]

In the case of oscillations of infinitesimal amplitude, (2.13a) reduces to

\[ C_m = f(\sigma_m) + \xi \xi' \sigma_m + \frac{\xi \xi}{V_\infty} g(\sigma_m) \quad (2.13b) \]

It is now clear that the functions \( f'(\sigma_m) \) and \( g(\sigma_m) \) are related to the stiffness derivative \( S(\sigma_m) \) and the damping-in-pitch derivative \( D(\sigma_m) \) at an angle of attack \( \sigma_m' \), as defined in classical aerodynamics, by

\[ f'(\sigma_m) = -S(\sigma_m), \quad g(\sigma_m) = -D(\sigma_m) \quad (2.14) \]

Comparing (2.13a) and (2.13b), we conclude that knowing the stiffness and damping derivatives from the results of calculations for oscillations of
infinitesimal amplitude enables one to obtain immediately the pitching-moment coefficient $C_m$ for the corresponding finite-amplitude case. This general conclusion is supported by the form of the exact solution for $C_m$ for the wedge oscillating at large amplitude given in [10]. (To correct a misprint in [10], a term $hA_a [\cos(\theta - \theta_a) - 1]$ should be added to the right-hand side of Eq. (12b) in [10].)

Having determined an appropriate form of $M(t)$ for use in the inertial equations of motion (2.1), we now rewrite the equations introducing (2.13a) along with dimensionless time (i.e., characteristic lengths of travel) $\tau = V_\infty t/\lambda$. (Note that we shall retain the symbol ('') to designate a time derivative. Henceforth, however, the derivative will be with respect to dimensionless time: ('') $\equiv d/d\tau$.) Let

$$F(\xi, \dot{\xi}, \sigma_m) = \frac{M(\tau)}{I(V_\infty/\lambda)^2} = \kappa [C_m(\xi, \dot{\xi}, \sigma_m) - C_m(0, 0, \sigma_m)]$$

$$= \kappa [f(\sigma_m + \xi) - f(\sigma_m) + \dot{\xi}g(\sigma_m + \xi)] (2.15)$$

with

$$\kappa = \frac{\rho_\infty S \bar{\alpha}^3}{2I}, \quad \xi = \frac{d\xi}{d\tau}$$

The inertial equations of motion become

$$\frac{d\xi}{d\tau} = \dot{\xi}; \quad (2.16a)$$

$$\frac{d\dot{\xi}}{d\tau} = F(\xi, \dot{\xi}, \sigma_m); \quad (2.16b)$$

An expansion of $F(\xi, \dot{\xi}, \sigma_m)$ in a Taylor series in $\xi$ and $\dot{\xi}$ and a change of notation $u_1 = \xi, u_2 = \dot{\xi}$ yields for (2.16)
\[ \dot{u}_j = A_{ij}(\sigma_m)u_j + B_{ijk}(\sigma_m)u_ju_k + C_{ijk\ell}(\sigma_m)u_ju_ku_\ell + O(|\dot{u}|^4), \quad (i = 1,2) \] (2.17)

where

\[ A = \begin{pmatrix} 0 & 1 \\ -\kappa S(\sigma_m) & -\kappa D(\sigma_m) \end{pmatrix} \] (2.18a)

\[ B_{ijk} = 0, \quad B_{2jk} = \frac{1}{2!} \frac{\partial^2 \Phi}{\partial u_j \partial u_k} \bigg|_{u=0} \] (2.18b)

\[ C_{1jk\ell} = 0, \quad C_{2jk\ell} = \frac{1}{3!} \frac{\partial^3 \Phi}{\partial u_j \partial u_k \partial u_\ell} \bigg|_{u=0} \] (2.18c)

(Although (2.16a,b) have been derived on the assumption of slow oscillations (terms in \( C_m \) of \( O(\xi^2, \ddot{\xi}) \) omitted), our subsequent bifurcation analysis of (2.16) will hold for general \( F(\xi, \ddot{\xi}, \sigma_m) \), i.e., as if no restriction had been placed on the magnitude of \( \dot{\xi} \).

In (2.18) the tensors \( B \) and \( C \) represent the effects of finite amplitude to the second and third order. We note that the following symmetry properties hold:

\[ B_{2jk} = B_{2kj} \] (2.19a)

\[ C_{2jk\ell} = C_{2j\ell k} = C_{2k\ell j} = C_{2k\ell j} = C_{2k\ell j} = C_{2k\ell j} \] (2.19b)

On the basis of (2.17), we shall study the linear and nonlinear stability of the motion in subsequent sections.

3. LINEAR STABILITY THEORY. The stability of the steady motion at an angle of attack \( \sigma_m \) to infinitesimal disturbances is determined by the nature of the eigenvalues of the matrix \( A \). They are
\[ \lambda_2(\sigma_m) = \frac{1}{2} [-\kappa D(\sigma_m) \pm \sqrt{\kappa^2 D^2(\sigma_m) - 4\kappa S(\sigma_m)}] \] (3.1)

**Case I:** \( S(\sigma_m) < 0 \). In this case \( \lambda_1 > 0, \lambda_2 < 0 \). The steady motion at this angle of attack \( \sigma_m \) is always unstable.

**Case II:** \( S(\sigma_m) > 0 \).

**Case IIa:** \( D(\sigma_m) < 0 \). In this case \( \text{Re}(\lambda_1) > 0 \) and the steady motion at \( \sigma_m \) is unstable.

**Case IIb:** \( D(\sigma_m) > 0 \). In this case \( \text{Re}(\lambda_2) < 0 \) and the steady motion at \( \sigma_m \) is stable.

Thus, only in Case IIb, when both stiffness and damping-in-pitch derivatives are positive, is the steady motion at angle of attack \( \sigma_m \) stable to infinitesimal disturbances. In fact, stability theory [3] can be used to show that stability of the steady motion in this case is assured only if the disturbance is sufficiently small.

In all cases in which the linearized theory predicts growth of the disturbance amplitude, the growth predicted is of exponential form and hence must cease to be valid after some finite time when the amplitude is no longer small. Thus, what eventually happens to a motion for which linearized stability theory predicts an initial growth of disturbances cannot be determined from the linearized theory itself. Instead, the full nonlinear inertial equations of motion, or a suitable approximation of them, such as (2.16), must be adopted to determine the ultimate state of the motion. Of particular interest is the dynamic stability boundary \( \sigma_m = \sigma_{cr} \), where \( S(\sigma_{cr}) > 0, D(\sigma_{cr}) = 0 \). The stability characteristics near this boundary will be studied in the next section.
4. NONLINEAR STABILITY THEORY. At the dynamic stability boundary
\( \sigma = \sigma_{cr} \), we have \( S(\sigma_{cr}) > 0 \) and \( D(\sigma_{cr}) = 0 \), hence

\[
\lambda_1(\sigma_{cr}) = \pm i\sqrt{\kappa S(\sigma_{cr})} = \pm i\omega_0 \tag{4.1}
\]

The existence of purely imaginary eigenvalues of the matrix \( A \) at
\( \sigma_m = \sigma_{cr} \) is the characteristic sign of a Hopf bifurcation [3, 14],
signaling a changeover from stable steady motion to periodic motion.

On crossing \( \sigma_m = \sigma_{cr} \), the steady motion that had been stable for
\( \sigma_m < \sigma_{cr} \) will become unstable to disturbances, resulting (after a
transient motion has died away) in the existence of a new motion, which
(if it is stable) will be periodic. In the vicinity of \( \sigma_m = \sigma_{cr} \), the
circular frequency of the periodic motion will be nearly equal to \( \omega_0 \).
We call the new solution of the equations of motion a bifurcation solu-
tion. In this section we shall determine its character and a criterion
for its stability.

For \( \sigma_m \) slightly larger than \( \sigma_{cr} \), the eigenvalues of the matrix \( A \)
are

\[
\lambda_1 = -\frac{1}{2} \kappa D(\sigma_m) \pm i\Omega(\sigma_m) \tag{4.2}
\]

where

\[
\Omega(\sigma_m) = \sqrt{\kappa S(\sigma_m) - \kappa^2 D^2(\sigma_m)/4} \tag{4.3}
\]

We shall assume that

\[
D'(\sigma_{cr}) < 0 \tag{4.4}
\]
which is the usual case in applications [6]. (The case $D'(\sigma_{cr}) > 0$ can be treated in exactly the same way.) The normalized eigenvector $\xi(\sigma_m)$ associated with the eigenvalue $\lambda(\sigma_m)$ is

$$\xi(\sigma_m) = \begin{pmatrix} \xi_1(\sigma_m) \\ \xi_2(\sigma_m) \end{pmatrix} = \frac{1 - i}{2\sqrt{\lambda(\sigma_m)}} \begin{pmatrix} 1 \\ \lambda(\sigma_m) \end{pmatrix}$$

(4.5)

whereas the adjoint eigenvector $\xi^*(\sigma_m)$ with eigenvalue $\bar{\lambda}(\sigma_m)$, which is the complex conjugate of $\lambda(\sigma_m)$, is

$$\xi^*(\sigma_m) = \begin{pmatrix} \xi_1^*(\sigma_m) \\ \xi_2^*(\sigma_m) \end{pmatrix} = \frac{1 + i}{2\sqrt{\bar{\lambda}(\sigma_m)}} \begin{pmatrix} \bar{\lambda}(\sigma_m) + \kappa D(\sigma_m) \\ 1 \end{pmatrix}$$

(4.6)

A. Hopf Bifurcation. The bifurcation solution $\hat{u}(\tau, \sigma_m)$ may be written as

$$\hat{u} = a(\tau)\xi + \bar{a}(\tau)\bar{\xi}$$

(4.7)

Following Iooss and Joseph ([3], p. 125), we get

$$\begin{align*}
a &= \varepsilon b_1(s) + \varepsilon^2 b_2(s) + \varepsilon^3 b_3(s) + O(\varepsilon^4) \\
s &= [\omega_0 + \varepsilon^2 \omega_2 + O(\varepsilon^4)]\tau \\
\sigma_m &= \sigma_{cr} + \varepsilon^2 \sigma_m + O(\varepsilon^4)
\end{align*}$$

(4.8)

where, for brevity, we omit the lengthy solution forms for $\varepsilon$, $b_n$, $\omega_2$, and $\sigma_m$ (cf. [11]). The solution is periodic in $\tau$ with circular frequency equal to $\omega_0 + \varepsilon^2 \omega_2 + O(\varepsilon^4)$.

B. Stability of the Periodic Bifurcation Solution. According to Floquet theory [3], the stability of the periodic bifurcation solution (4.8) is determined by the sign of an index $\mu$. To $O(\varepsilon^4)$, $\mu$ has the form
and the periodic bifurcation solution is stable if \( \mu < 0 \), unstable if \( \mu > 0 \). Since we have assumed \( D'(\sigma_{cr}) < 0 \), stability thus depends on the sign of \( \sigma_{m2} \), with \( \sigma_{m2} > 0 \) denoting stability and \( \sigma_{m2} < 0 \) instability. It remains to cast \( \sigma_{m2} \) in more recognizable terms. After considerable manipulation, we get

\[
\mu = \frac{\varepsilon^2}{4\omega_0} \left[ \frac{\partial^2 F}{\partial u_1^2} + \omega^2 \frac{\partial^2 F}{\partial u_2^2} \right] \left. \left( \frac{\partial^2 F}{\partial u_1 \partial u_2} + \omega^2 \frac{\partial^2 F}{\partial u_2^2} \right) \right|_{u=0}^{\sigma = \sigma_{cr}}
\]

in terms of \( F(u_1, u_2, \sigma_m) \). From (2.15) we see that the function \( F \) is directly related to the pitching-moment coefficient \( C_m(\xi, \dot{\xi}, \sigma_m) \) acting on the aircraft which is performing a finite-amplitude pitching oscillation \( \xi \) around a mean angle of attack \( \sigma_m \). Equation (4.10) demonstrates that the stability of the periodic motion near the dynamic stability boundary \( \sigma_{cr} \) is determined by the behavior of the aerodynamic response \( C_m(\xi, \dot{\xi}, \sigma_m) \) in that vicinity.

With the assumption of slow oscillations under which the form of (2.15) was derived (terms of \( O(\varepsilon^2, \dot{\xi}) \) neglected), we may substitute (2.15) into (4.10) to get

\[
\mu = \frac{\varepsilon^2}{4\omega_0} \left( \varepsilon^2 \frac{\partial^2 f}{\partial \xi^2} \frac{\partial^2 g}{\partial \xi^2} + \kappa \omega_0^2 \frac{\partial^2 f}{\partial \xi^2} \frac{\partial^2 g}{\partial \xi^2} \right)_{\xi=0}^{\sigma = \sigma_{cr}}
\]

From (2.14) and the structure of the functions \( f \) and \( g \), we write
By using (4.2) and (4.12) in (4.11) (with \(S(\sigma_{cr}) > 0\)), we arrive at the simple form

\[
\mu = -\epsilon^2(S')^{1/2} \frac{d}{d\sigma_m} D' \Big|_{\sigma_m = \sigma_{cr}}
\]  

The simplicity of this result suggests that it might be possible to derive it by a less formal method. This is indeed the case: We have verified the result by a physical approach familiar to workers in the field of nonlinear mechanics.) Equation (4.13) reveals that the sign of \(\mu\), and thus the stability of the bifurcation solution, is independent of the scalar and inertial properties of the aircraft. Rather, stability depends only on whether the aerodynamic property \((D'/S)\) is increasing or decreasing on crossing the dynamic stability boundary \(\sigma_m = \sigma_{cr}\). The two possibilities are well illustrated in the form of bifurcation diagrams as shown in Figs. 1a and 1b.

In a bifurcation diagram, the abscissa represents the parameter that is being varied, in our case the mean angle of attack \(\sigma_m\). The ordinate is a parameter characteristic of the bifurcation solution alone. In our case it is \(\epsilon\), a measure of the amplitude of the periodic bifurcation solution. Stable solutions are indicated by solid lines, unstable solutions by dashed lines. Thus, over the range of mean angle of attack \(\sigma_m < \sigma_{cr}\) where the steady-state motion is stable, \(\epsilon\) is zero, and the
stable steady motion is represented along the abscissa by a solid line. The steady motion becomes unstable for all values of $\sigma_m > \sigma_{cr}$ as the dashed line along the abscissa indicates. Periodic solutions bifurcate from $\sigma_m = \sigma_{cr}$ either supercritically or subcritically.

When $\left.\frac{d}{d\sigma_m}(D'/S)\right|_{\sigma_m=\sigma_{cr}} > 0$ (implying $\sigma_{m2} > 0$), the bifurcation is called supercritical and its characteristic form is shown in Fig. 1a. Stable periodic solutions (solid curves in Fig. 1a) exist for values of $\sigma_m - \sigma_{cr} > 0$. The amplitude of the periodic solution at a given value of $\sigma_m - \sigma_{cr}$ is proportional to $\epsilon$, hence is vanishingly small when $\sigma_m - \sigma_{cr}$ is small, varying essentially as $(\sigma_m - \sigma_{cr})^{1/2}$.

When $\left.\frac{d}{d\sigma_m}(D'/S)\right|_{\sigma_m=\sigma_{cr}} < 0$ (implying $\sigma_{m2} < 0$), the bifurcation is called subcritical and its characteristic form is shown in Fig. 1b. Periodic solutions exist for values of $\sigma_m - \sigma_{cr} < 0$, but they are unstable (dashed curve in Fig. 1b). Whether stable periodic solutions do or do not exist for $\sigma_m > \sigma_{cr}$ depends predominantly on the behavior of the damping-in-pitch derivative $D(\sigma_m)$ for $\sigma_m > \sigma_{cr}$. If no such stable periodic solutions exist for $\sigma_m > \sigma_{cr}$, then when the mean angle of attack $\sigma_m$ is increased beyond $\sigma_{cr}$ the aircraft may undergo an aperiodic motion whose departure from the steady motion at $\sigma_m = \sigma_{cr}$ is potentially large.

In the more likely event that stable periodic solutions do exist for $\sigma_m > \sigma_{cr}$ (an example is given later), their amplitudes must be finite, and not infinitesimally small, even for small positive values of $\sigma_m - \sigma_{cr}$. It is likely that this branch of stable periodic solutions will join that of the unstable branch in the way illustrated in Fig. 1b.
In this event, the form of the bifurcation curve for values of $\sigma_m < \sigma_{cr}$ helps explain the situation mentioned earlier, where it was noted that the steady-state motion could be stable to sufficiently small disturbances but become unstable to larger disturbances. Thus, Fig. 1b suggests that for $\sigma_m < \sigma_{cr}$, so long as disturbances are of small enough amplitude to lie below those of the unstable branch of periodic solutions (curve OB in Fig. 1b), they will die out with time and the steady motion will remain stable. However, disturbances with amplitudes sufficiently larger than those of the unstable branch may actually grow up to the ultimate motion as $t \to \infty$, which will be that of the stable branch of periodic solutions (curve BA in Fig. 1b). Finally, we note that if the motion does attain the stable branch of periodic solutions (say, for $\sigma_m < \sigma_{cr}$) then hysteresis effects will manifest themselves with further changes in $\sigma_m$. When $\sigma_m$ is increased beyond $\sigma_{cr}$, the motion will continue to be periodic with finite amplitude (point A in Fig. 1b). If $\sigma_m$ is now decreased below $\sigma_{cr}$, the periodic motion will persist, even at values of $\sigma_m$ where previously there had been steady motion when $\sigma_m$ was being increased. Not until $\sigma_m$ is diminished beyond a certain point (point B in Fig. 1b) will the motion return to the steady-state condition (point C in Fig. 1b) that had been experienced when $\sigma_m$ was increasing.

To further explore the implications of (4.13), we invoke some approximate relationships between the damping-in-pitch derivative $D(\sigma_m)$ and the stiffness derivative $S(\sigma_m)$. Tobak and Schiff have argued (see, in particular, [15]) that, to good accuracy, a linear relationship should
exist between \( D \) and \( S \) at any value of \( \sigma_m \); i.e., \( D(\sigma_m) \approx a - bS(\sigma_m) \), with \( b > 0 \). In addition, we require that \( D \) vanish at \( \sigma_m = \sigma_{cr} \).

The two requirements yield the form
\[
D(\sigma_m) = b[S(\sigma_{cr}) - S(\sigma_m)], \quad b > 0 \tag{4.14}
\]

(The validity of the approximate relation (4.14) has been verified in the present study (via comparison with exact results in [7]) for use with oscillating flat-plate airfoils in supersonic/hypersonic flow and in [12] for use with oscillating flaps in transonic flow.) Replacing \( D \) in (4.13) by (4.14) casts the criterion solely in terms of \( S \):
\[
\mu = \frac{c^2(\kappa S)^{1/2}b}{4} \frac{d^2}{d\sigma_m^2} \left[ 2n S(\sigma_m) \right] \bigg|_{\sigma_m = \sigma_{cr}} \tag{4.15}
\]

Thus, near \( \sigma_m = \sigma_{cr} \), if the stiffness derivative \( S(\sigma_m) \) increases with \( \sigma_m \) slower/faster than exponential, the periodic bifurcation solution is stable (supercritical)/unstable (subcritical). Cast in terms of \( D \) instead of \( S \), the criterion states that decreasing \( D \) with respect to \( \sigma_m \) slower/faster than exponential results in stable (supercritical)/unstable (subcritical) periodic bifurcation solutions.

Examples of \( S(\sigma_m) \) and \( D(\sigma_m) \) that obey (4.14) and exhibit the various possibilities are as follows.

Example 1:
\[
\begin{align*}
S_1(\sigma_m) &= S_0 \exp[k(\sigma_m - \sigma_{cr}) + m(\sigma_m - \sigma_{cr})^2] \\
D_1(\sigma_m) &= bS_0 \{1 - \exp[k(\sigma_m - \sigma_{cr}) + m(\sigma_m - \sigma_{cr})^2]\}
\end{align*}
\tag{4.16}
\]
Example 2:

\[
\begin{align*}
S_2(\sigma_m) &= S_0 \exp[k(\sigma_m - \sigma_{cr}) + m(\sigma_m - \sigma_{cr})^2 - n(\sigma_m - \sigma_{cr})^4] \\
D_2(\sigma_m) &= bS_0[1 - \exp[k(\sigma_m - \sigma_{cr}) + m(\sigma_m - \sigma_{cr})^2 - n(\sigma_m - \sigma_{cr})^4]]
\end{align*}
\]

(4.17)

where \( S_0, k, \) and \( n \) are positive constants. According to (4.15), \( m > 0 \) corresponds to unstable periodic bifurcation solutions (subcritical bifurcation), and \( m < 0 \) corresponds to stable periodic bifurcation solutions (supercritical bifurcation). In the case of subcritical bifurcation \( (m > 0) \) in Example 1, the damping-in-pitch derivative \( D_1(\sigma_m) \) continues to decrease to very large negative values as \( (\sigma_m - \sigma_{cr}) \) increases, which makes it very unlikely that the system (2.16) will have a stable periodic motion as a solution for \( \sigma_m > \sigma_{cr} \). On the other hand, in Example 2 the damping-in-pitch derivative \( D_2(\sigma_m) \) becomes positive for sufficiently large \( |\sigma_m - \sigma_{cr}| \) so that a stable periodic motion may be a possible solution for \( \sigma_m > \sigma_{cr}, m > 0 \). Indeed, \( S_2 \) and \( D_2 \) in Example 2 fulfill all of the conditions set by a theorem of Filippov [16], the satisfaction of which guarantees the existence of a stable periodic motion of the system (2.16) for \( \sigma_m > \sigma_{cr} \). As we have noted, resulting as it does from a subcritical bifurcation, the solution will exhibit hysteresis effects with variations in \( \sigma_m \) below \( \sigma_{cr} \).

5. SUPERSONIC/HYPersonic FLAT-PLATE AIRFOILS. To illustrate the application of bifurcation theory in a concrete case, we consider a flat-plate airfoil in supersonic/hypersonic flow. The stiffness derivative \( S(\sigma_m) \) and the damping-in-pitch derivative \( D(\sigma_m) \) are known as
analytic functions of $\sigma_m$ up to the angle-for-shock detachment [6-8]. They depend on the flight Mach number $M_\infty$, the ratio of specific heats $\gamma$ (here taken to be that of air, $\gamma = 1.4$), and the (dimensionless) distance $h$ of the center of gravity from the leading edge, here taken as a fraction of the chord length $c$. Results are presented in Fig. 2 of $\log S(\sigma_m)$ versus $\sigma_m$ (with $M_\infty = 2.0$, $h = 0$) and in Table 1 of the index $\mu$ for various combinations of $M_\infty$ and $h$. It is shown in Fig. 2 that $S(\sigma_m)$ increases faster than exponential near $\sigma_m = \sigma_{cr} = 15.75^\circ$, and in Table 1 that $\mu$ is always positive. We conclude that whenever the flat-plate airfoil becomes dynamically unstable [$D(\sigma_{cr}) \equiv 0$], the ensuing bifurcation always will be subcritical.

Accordingly, there are two possibilities. One, a subcritical bifurcation curve such as that sketched in Fig. 1b exists, in which case the airfoil motion will find stability at values of $\sigma_m > \sigma_{cr}$ in a periodic oscillation of finite amplitude. At values of $\sigma_m < \sigma_{cr}$, the steady-state motion will be stable for small disturbances, but for larger disturbances the airfoil motion will again seek the stable periodic motion. Exchanges between these two stable modes at $\sigma_m < \sigma_{cr}$ will be accompanied by hysteresis effects. Two, alternatively, a bifurcation curve such as that sketched in Fig. 1b does not exist, in which case a potentially large aperiodic departure from the steady-state motion may occur as $\sigma_m$ exceeds $\sigma_{cr}$. In either case, on exceeding $\sigma_{cr}$ the loss of stability of the steady-state motion must entail a discrete change to a new stable condition.
6. CONCLUDING REMARKS. Bifurcation theory has been used to analyze the nonlinear dynamic stability characteristics of an aircraft subject to single-degree-of-freedom pitching-motion perturbations about a large mean angle of attack. Setting up the equations to which the bifurcation theory was applied required, first, determining conditions under which the inertial equations of motion and the gas-dynamic equations governing the flow could be decoupled and, second, showing how the required aerodynamic responses to finite-amplitude oscillations could be obtained from the responses to infinitesimal-amplitude oscillations.

Results of the bifurcation theory analysis revealed that when the mean angle of attack is increased past the critical point where the aerodynamic damping vanishes, new solutions describing finite-amplitude periodic motions bifurcate from the previously stable steady motion. The sign of a simple criterion, cast in terms of aerodynamic properties, determines whether the bifurcating solutions are stable (supercritical) or unstable (subcritical). For flat-plate airfoils flying at supersonic/hypersonic speed, the bifurcation is subcritical, implying either that exchanges of stability between steady and periodic motions will be accompanied by hysteresis phenomena, or that a potentially dangerous aperiodic motion may develop. In either case the loss of stability of the steady-state motion must be accompanied by a discrete change to a new stable state.

Fig. 1
Fig. 2
Bifurcation theory is used to analyze the nonlinear dynamic stability characteristics of an aircraft subject to single-degree-of-freedom pitching-motion perturbations about a large mean angle of attack. The requisite aerodynamic information in the equations of motion can be represented in a form equivalent to the response to finite-amplitude pitching oscillations about the mean angle of attack. It is shown how this information can be deduced from the case of infinitesimal-amplitude oscillations. The bifurcation theory analysis reveals that when the mean angle of attack is increased beyond a critical value at which the aerodynamic damping vanishes, new solutions representing finite-amplitude periodic motions bifurcate from the previously stable steady motion. The sign of a simple criterion, cast in terms of aerodynamic properties, determines whether the bifurcating solutions are stable (supercritical) or unstable (subcritical). For flat-plate airfoils flying at supersonic/hypersonic speed, the bifurcation is subcritical, implying either that exchanges of stability between steady and periodic motion are accompanied by hysteresis phenomena, or that potentially large aperiodic departures from steady motion may develop.
