I. INTRODUCTION

We have used the Dataflow Simulation System (DFSS) at USL as the medium on which we have produced a functional simulation of SIFT. DFSS is written in PL/I and is supported by MULTICS. Within the simulation, all the interprocessor communication, fault simulation, system state data, and monitoring were implemented in dataflow and supported directly by DFSS. The actual processor level computation was carried out by the SIFT code in PASCAL. The interface between DFSS in PL/I and the SIFT code in PASCAL was supported under a mechanism in DFSS called a Node Realization Module (NRM).

There were several reasons for making these choices for this initial simulation. The first reason was that these choices allowed us to effectively use the SIFT code that was available. Also, DFSS supported the addition of appropriate monitoring and fault simulation mechanisms. Another reason involved the fact that this preliminary simulation should point out some of the limitations of the current dataflow simulator and provide useful information in designing the new dataflow simulator in PASCAL. The primary reason for using dataflow only at the highest levels of SIFT was related to the way interprocessor communication took place in the last version of SIFT. Virtually any procedural process can be simulated in dataflow on DFSS. However, as a system simulation medium, dataflow worked best in dealing with parallel, asynchronous, communicating processes.
This report is divided into three sections and each of these sections describes different phases of the simulation of SIFT on DFSS. Section II outlines briefly the changes that have been made to the SIFT code so that the program could be run on the PASCAL compiler at USL. Section III gives the interface mechanism between the SIFT code in PASCAL and the PL/I program. This is necessary to include SIFT code as a node within the dataflow graph. In section IV the simulation of a single processor on the DFSS is described with the basic structure of the node. This section also describes an approach to the simulation of the complete system with \( n \) (\( n=5 \)) processors. The interprocess communication buffers are concurrent access files with each of the processors having access to them as required by the operating system. This is achieved by means of the a PL/I interface program. The details are given in the specific section.

II. SIFT PASCAL CODE

Some functions in SIFT code were realized in the assembly language of BDX 930. In order to obtain the same kind of accuracy of numerical values computed by these functions, they were translated into PL/I. PL/I was used mainly to utilize the range of options available in obtaining the required accuracy.

The language dependent routines BAND (bitwise 'and') and BOR (bitwise 'or') were written in PL/I. To use these PL/I routines the statements containing the actual functions were modified.
For example:  \[(\text{framecount mod scheds[vp+1]})\]
was changed to
\[\text{mod(framecount,scheds[vp+1])};\]

\[(\text{eofbit band dbx*8})\]
was changed to
\[\text{band(eofbit,dbx*8});\]

Another change was made to the code. All the location
dependent variables were made independent of the system. The
'at' construct used in the original code was not present in
either version of PASCAL compilers available at USL. So these
variables were made independent of the locations in memory. In
fact, because of the virtual memory system on MULTICS, no
construct forcing static memory location is available. This
problem is overcome simply by removing the 'at' \{location\} from
the variable declaration part.

For example:  \[\text{dbfile at dbloo : integer};\]
is changed to
\[\text{dbfile : integer};\]

The system dependent routine 'gprocessor' is not necessary
because the processor id could be initialized at the beginning of
the process. The new version of the SIFT code is in Appendix I.
III. INTERFACE PROGRAM

In order to realize the node realization module as described in [1], we used a PL/I program which called the SIFT code as a subroutine and there should be a correspondence between the two. While passing the parameters of type array or structure (record), a pointer to an array or a structure was passed. An array or a structure of same type was declared in the PL/I program with a pointer. This pointer was then equated to the external pointer (PASCAL pointer).

An example to reflect the parameter passing mechanism is given:

PASCAL declaration: dffile : array(0:1023) of integer;
                dfptrpas:

PL/I declaration: dol dfile(0:1023) fixed bin(35) based(dfptr);
                dfptr = dfptrpas;

With the above statement, any reference to the PL/I array element was reflected in the corresponding PASCAL array. All the other simple variables were external. This program is in Appendix II.

This PL/I program also realized the interprocessor communication through a procedure which was called whenever the transaction pointer in the "broadcast" or "stobroadcast" routine of the SIFT code was set. The interprocessor buffers were concurrent access files and these could be accessed and checked after every subframe.
IV. SIMULATION OF SIPT ON DPSS

Each individual processor node within the dataflow graph of complete system is given in figure 1. The dataflow program to realize this basic node is given in Appendix - III. With each of these nodes representing a processor, complete simulation with n (5) processors was attempted. Each processor was supposed to execute the current schedule: compute, broadcast, and vote according to schedule and assume that the other processors are also doing the same thing. The behavior of a processor is not immediately changed if communication breaks down or computation faults occur. The only changes in the behavior of the processor, caused by failures in interprocessor communication, are long term. If failures take place, eventually a reconfiguration will occur.

The error buffer data and the data buffer values could be examined through the PL/I interface program at the end of every subframe.

The details of the scheduling tables could not be worked out as expected due to the fact that these were written in assembly language of BDIX 930. In effect, the bottleneck in implementing the simulation was the scheduling tables.
ON DATA FLOW SIMULATOR

The major responsibility of the research team at the University of Texas at Arlington was the design of a data flow language and a data flow simulator for this language written in Pascal for VAX/780 system.

DFDLS (pronounced as daffodils) is such a data flow simulator written in Pascal and at present is available on DEC 20 system. It will be available on VAX/780 soon. Simulation of computer systems, both hardware and software, can be performed using data flow concepts. For an introduction to data flow, the reader is referred to [1].

The major features of DFDLS are given below.

1. Tokens on data flow arcs can be structured data items. Existing data flow computers and languages permit only elementary data types like integer, real and characters. DFDLS allows all the Pascal data types. At this time, record data types are not processed, but will be included soon.

2. Firing set semantics can be specified in DFDLS. In the basic data flow, a node is enabled for execution only when all input arcs contain tokens and no tokens are present on the output arcs. This firing semantics are extended in DFDLS by describing alternate firing sets. Each set defines the mandatory input values required for the node to execute.

3. Nodes in DFDLS can be data flow subgraphs. In most of the existing data flow systems only primitive functions such as ADD two numbers are permitted. In our system, a node can be a primitive function defined by the system, a data flow subgraph or a Pascal procedure provided by the user. These Pascal procedures are linked dynamically by the runtime environment.

4. The input language is very simple. DFDLS interprets simulation models expressed in our textual language. There is a one-to-one correspondence between the data flow graphs
and the textual representation. Thus, data flow graphs can be translated directly into the input language. This also provides for graphical interface that can be designed at a later date.

5. Block structures and Recursion: The present implementation of DFDLS permits a restricted block structure in that, all names must be unique. Recursion is not allowed. However, we are in the process of extending DFDLS to allow more general nesting of blocks and recursion. Because of our data structures and modular design of DFDLS, this addition is straightforward. Separate descriptor tables and node tables will be created for each block and display stack will be used to implement recursion and static scopes.

A complete description of DFDLS and a detailed outline of the design can be found in [3].

We made every attempt to complete the design and testing of DFDLS on VAX/780 before the end of 1983. However, due to unforeseen problems, we are only able to complete the design and test DFDLS on DEC 20. We would like to describe briefly the technical problems faced by the research team at UTA.

Due to the policies of the board of Regents of the state of Texas, the acquisition of VAX was delayed by several months. The hardware had arrived at UTA in December 1983. We are awaiting the installation of a new air-conditioning equipment before bringing up the VAX system.

The university and the department of Computer Science and Engineering have seen significant increases in the enrollment. The computing facilities are not adequate to handle the increase, resulting in severe restrictions on the use of disk space, access to terminals and in general, degraded response time.
The current version of DFDLS is being implemented on DEC 20/60 computer system, awaiting the arrival of VAX 780. Although most of the code for DFDLS is written in Pascal and thus portable, the section that dynamically links user supplied Pascal procedures with the runtime environment of DFDLS is very machine dependent and must be rewritten for VAX.

During the execution of a data flow program, the function of a data flow node can be realized by invoking either system provided Pascal procedures (Library functions) or user provided procedures. This facility enables us to add reliability calculations to the simulator. There is no easy way of linking programs dynamically on DEC 2060 system. Several alternatives have been considered and discarded due to the complexity of implementation.

A dynamic linker could be written with DFDLS to interface with the standard DEC linker provided. This requires significant amount of code in Macro-assembler for DEC 2060. Since DFDLS will be transported to VAX, this solution was discarded. Pascal procedures could be added to the DFDLS and the entire system could be recompiled and linked for each run. This solution was not entertained because of the inefficiency.

Our next choice was to have the NRM (node realization module) to invoke the user supplied procedure as a separate task with the data space mapped into the data space of DFDLS. It was hoped that this option would allow access to parameters similar to call by
reference technique. However, two problems exist with this method. Sharing of data space is not possible because the sub-process (corresponding to the user supplied procedures) would overlay the DFDLS space resulting in the destruction of crucial data belonging to the simulator. The second problem arises from the fact that in order to invoke sub-tasks, it is necessary to make user procedures as independent programs. This would require that the user write programs instead of procedures to link with the runtime environment of DFDLS.

Despite of the restrictions imposed by the last solution, we have decided to pursue this approach in implementing DFDLS on DEC 2060. We will relax these restriction in VAX 780 implementation. In the present solution to the linking problem, user supplied Pascal procedures are made into complete programs and DFDLS will communicate with these programs through standard disk files. The parameters are written into files and read from files by both user programs and DFDLS.
2. REPORT ON RELIABILITY MODELS FOR DATA FLOW

The research team at UTA has also attempted to develop reliability models for data flow graphs, so that the reliability of computer systems modeled as data flow graphs can be predicted. To our knowledge there exists no published reliability studies of data flow systems. A survey of related models can be found in [3].

A recursive algorithmic method can be used to determine the reliability of a data flow graph. The reliability of the output from a node depends on the reliabilities of the inputs to the node and the reliability of the node itself.

\[
R(0) = g( f( R_1, R_2, \ldots, R_N ), R_{\text{node}} ) \quad (1)
\]

FIG. 1 RELIABILITY OF A DATA FLOW NODE
Here $f$ is a combinatorial function describing the input configuration of the node. $R_1$, $R_2$, ..., $R_N$ are the reliabilities of the inputs and $R_{node}$ is the reliability of the node. The node in the above calculation can be a subgraph, thus providing for a recursive definition.

2.1 Our Approach:

We have developed a method that combines Markov processes with the recursive algorithmic method described above. A path from an input of a data flow graph to an output of the data flow graph is defined as the alternating sequence of arcs and nodes, $a_1$, $n_1$, $a_2$, $n_2$, ..., $a_o$, where $a_1$ is the input arc and $a_o$ is the output arc. The reliability of the path can be determined using Markov methods.

A significant structural property of a data flow system is its capability for parallel processing with split and merge of job streams at various levels. This leads to multiple parallel paths between an input to the data flow graph and an output from the data flow graph. The parallel paths need not be independent. The dependencies will be handled by the algorithmic method.

For example, let there be $M$ parallel paths between a given input and output of the system. Let $R$ be the overall reliability of the output with respect to the given input, which is to be determined. Also, suppose $R_1$, $R_2$, ..., $R_M$ be the corresponding reliabilities of the $M$ parallel paths, obtained using Markov methods. Then $R$ is given by
where \( g \) is the function describing the inter-relationships between the parallel paths.

The reliability measure of the entire system can be obtained by calculating the reliabilities of all outputs from the system with respect to every input to the system. We are currently working with this method and developing the algorithms required to compute the inter-relationships between the parallel paths.
