1. SUMMARY

The major objective of this contract is to improve web base material with a goal toward obtaining solar cell efficiencies in excess of 18% (AM1). The program consists of the investigation of carrier loss mechanisms in web silicon, development of techniques to reduce carrier recombination in web, and web cell fabrication using effective surface passivation.

During this period the effect of stress on web cell performance has been investigated. Preliminary data indicate that stress has no appreciable influence on the minority-carrier diffusion length in the as-grown web crystals. The diffusion length was found to be about 30 ± 10 µm in the web crystals with a stress level of 40 MDyne/cm², as well as in the web crystals with stress of less than 5 MDyne/cm². This is probably because the diffusion length in the as-grown web is limited by quenched-in defects or impurities. However, after heat treatment (boron diffusion), the low-stress web showed very significant improvement in the diffusion length. Diffusion lengths as high as 116 µm were measured by the surface photovoltage technique in the low-stress web after heat treatment, while in the high-stress web there was no appreciable change in the diffusion length after heat treatment.

A web solar cell run has also been completed. Due to some processing problems, the fill factors were low and cell efficiencies were only in the range of 3-5%. More web runs are in progress.

The impurity-twin-plane interaction has been investigated by conducting DLTS measurements as a function of depth on titanium-doped web crystal. Initial results indicate that the grown-in titanium impurity tends to pile up near the twin plane. About a factor of five
increase in the Ti deep-level concentration was observed near the twin planes relative to the web surface.

Electron beam-induced current (EBIC) measurements have been performed on beveled web samples to detect any recombination activity at the twin planes within the web material. Preliminary EBIC measurements indicate that twin planes in web show higher recombination activity compared to the rest of the bulk; however, this recombination activity can vary appreciably along the length of the web crystal. Although this first set of EBIC measurements suggests that on the average the twin planes in the Ti-doped web crystal are less active, it is not clear that this observation has anything to do with Ti impurity. The variation in recombination activity along the twin planes suggests that the observed difference in the twin plane activity in the Ti-doped and baseline samples could be seen in different baseline web crystals. In addition, the DLTS measurements as a function of depth indicate an increase in the titanium deep-level concentration near the twin planes, which should, if anything, tend to increase recombination activity near the twin planes. More EBIC measurements on different web crystals are being planned to obtain a better understanding of this phenomenon.

It is important to realize that although some recombination activity has been detected at the twin planes by EBIC measurements, it is not known at this time how much impact, if any, this has on cell efficiency. In the future, an attempt will be made to correlate the two.
2. INTRODUCTION

The idealized efficiency (3) of a silicon solar cell is about 25%, assuming the best materials and surface parameters achievable to date, although present day cells fall considerably short of this limiting value. This is largely a consequence of heavy doping effects, bandgap narrowing, and high recombination at and near the cell surfaces. The major problems of efficiency improvement fall in the above categories; however, additional design requirements are essential for efficient contacts and antireflective coating. Although these areas are well understood, they are not insignificant and must be optimized consistent with device structure.

Starting material is equally important for high-efficiency cells because device fabrication and design are academic if the starting material quality is poor or it degrades rapidly with processing. The objective of this program is to understand and improve web silicon so that high-efficiency web cells can be fabricated using advanced cell design and processing.

It is clear that high efficiency is a major attribute that will enhance the large-scale applicability of photovoltaic systems. Systems calculations indicate that for very large-scale terrestrial applications, ≥15% efficient photovoltaic modules will be required at a cost of $0.50/watt. This implies that ≥18% efficient cells will be needed at low cost. Dendritic web silicon is a single-crystal silicon ribbon that has great potential for low-cost and high-efficiency solar cells. In this program we are trying to understand the loss mechanisms in dendritic web silicon by investigating the electrical activity of twin planes, the role of impurities and defects in web, impurity interaction with twin planes, starting web material quality, and the effect of heat treatment.
and gettering on web quality. An improved understanding of the above effects should lead to fabrication of ~18% efficient web cells with good uniformity. This second quarterly describes progress toward the development of high-efficiency solar cells on web silicon.
3. TECHNICAL PROGRESS

3.1 Effect of Residual Stress on Web SPV Diffusion Length

Investigations have begun regarding the relationship between residual stress and minority-carrier diffusion length in web material. Web material was acquired that has a "zero" residual stress, i.e., residual stress which has a magnitude less than 5 MDyne/cm². In addition, the "zero" stress material also has a low (Sirtl) etch pit density, indicating a low dislocation density. The diffusion length was measured on three web crystals with different residual stress and etch pit density, both in the as-grown state and after a BBr₃ diffusion at 960°C. The results are summarized in Table 1. The as-grown diffusion length ranged from 9 to 40 µm. Surprisingly, the R-461 samples had the lowest diffusion length, as-grown, in spite of having the lowest etch pit density and "zero" stress. However, after the samples had gone through boron diffusion, the Z-025 material, which had the highest residual stress and etch pit density, showed no improvement, while the "zero" stress Z-028 and R-461 material improved substantially in several cases. Perhaps the most dramatic improvement was observed for sample R-461-5.13, where the diffusion length increased from 10 µm, as-grown, to 83 µm after boron diffusion.

The reproducibility of the SPV measurement is typically 10% and occasionally 20%, as determined by repeating the measurement without changing the position of the SPV probe. However, after BBr₃ diffusion the diffusion length was observed to vary over the surface of a web sample approximately 3 cm x 3 cm in size. For example, at four points of the Z-028-12.16 sample the measured values were 56, 110, 123, and 162 µm. This indicates that the web material quality was somewhat nonuniform in cases where the diffusion length had reached a high

value. The samples listed in Table 1 are to receive a POC13 diffusion
and then be processed into finished cells. The SPV diffusion length
will be measured after the 850°C POC13 diffusion and after the cell is
completed to see if the diffusion lengths measured after BBr3 diffusion
are maintained.

At this time it appears that web material, as-grown, has a
diffusion length which may be much different from the diffusion length
in the finished cell. Structural imperfections, as revealed by etch
pits, may play a role in the way web material responds to high-tempera-
ture processing steps. The observation from the three web crystals that
were examined is that the diffusion length tended to improve with the
960°C diffusion for web material with low residual stress, and not for
material with high residual stress.

3.2 Dendritic Web Silicon Solar Cell Fabrication

The first web solar cell run was completed with planar geometry
and oxide surface passivation. Due to some processing problems, the
majority of the cells had low fill factor and cell efficiency only in
the range of 13-15%. Lighted I-V data for some representative cells
from this run are shown in Table 2. Cells with low fill factor
generally showed high series resistance which remained even after
sintering. Some more web runs have been initiated and the data from
this run are being analyzed.

3.3 Interaction Of Twin Planes With Grown-In Impurities

3.3.1 DLTS Measurements on Schottky Barrier Diodes Fabricated on
Beveled Web Surface

An experiment has been designed to determine if impurities tend
to be gettered by the twin planes in dendritic web silicon. Web
material (p-type) has been grown with harmful impurities intentionally
introduced by contaminating the silicon melt. Titanium and vanadium
impurities were grown-in since the trap parameters of these impurities

*FZ cells were fabricated with the web run.

Schottky diodes, in the form of stripes, were fabricated by depositing Ti/Au on a beveled web surface as shown in Figure 1. DLTS measurements, performed on the stripe covering the twin plane and on adjacent stripes, provides a profile of the trap concentration. If impurities do pile up at the twin plane and remain electrically active, a profile as shown in Figure 1 will be observed.
Use a Grown-In Impurity (Ti, V) as an Internal Tracer

Observe Trap Density as a Function of Distance from Twin Plane, Both As-Grown and After Processing (Including Gettering)

Compare Web Having High Diffusion Length with Web Having Low Diffusion Length (As Determined by SPV) Using this Technique

Figure 1. DLTS detection and identification of impurities piled up at the twin plane.
To date, approximately ten 2 x 5 mm pieces have been cut from the Ti-doped web crystal. These pieces have been beveled at an angle of 2° 52' and polished to remove surface damage. Part of the beveled surface was then etched to reveal the location at which the twin planes emerged from the beveled surface. A photograph of one such sample is shown in Figure 2.

A mask was designed and fabricated for this purpose. The width of the stripes is 125 μm and the spacing is 25 μm, giving a depth resolution of 7.5 μm from stripe to stripe. There are 30 stripes in a set, and the mask has stripe lengths of 1.0 mm, 1.5 mm, and 2.0 mm to accommodate samples of different size. The mask layout is shown in Figure 3. In addition to the stripes, larger rectangles are included in the mask to aid in proper alignment of the stripes with the twin plane.

In addition to the Ti-doped web samples, standard silicon web samples were also cut and beveled for comparison. After deposition of the DLTS stripes, the samples were mounted in a TO-5 header for the DLTS measurements.

On the as-grown titanium-doped web material (J167-1.1), the diffusion length was measured by the surface photovoltage technique to be 22 μm, compared to the diffusion length in standard as-grown web material, which falls in the range of 8 to 74 μm. Thus, the diffusion length is low for titanium-doped web but not extraordinarily low, suggesting that the concentration of titanium in the web was not extremely large. In order to measure this concentration, a conventional DLTS measurement was made using a 30-mil diameter Schottky diode as the test device. This dot, consisting of titanium and gold, was evaporated directly on the as-grown silicon surface. The results are shown in Figure 4, where two DLTS peaks are evident. Several scans were made in order to calculate the energy level associated with each peak, although only one scan is shown in Figure 4. The position in temperature and the energy level associated with peak 2 agree with those previously obtained for titanium in silicon. The concentration of titanium is 1.7 x 10^{12} cm^{-3},
Figure 2. Optical photograph (50X) of beveled sample for Ti-doped web crystal J167-1.1 (run TP-3, sample T-1).
Figure 3. Mask for twin plane activity.
Figure 4. DLTS scan for Ti-doped web crystal J167-1.1, as grown. Test device is a 30-mil Schottky dot.
which is only a factor of five above the detection limit of $3.5 \times 10^{11}/\text{cm}^3$ for 5 ohm-cm material. The source of peak 1 in Figure 4 at this time is not known.

DLTS measurements were then made on a beveled sample with titanium doping. In this case the Schottky diode was in the shape of a stripe 125 x 1000 μm in size. The stripes were defined by photolithography and were placed on the beveled surface as well as on the unbeveled, as-grown surface. One stripe was located directly over the line at which the twin planes emerged from the beveled surface.

Attempts were made to make DLTS measurements at three stripes (Figure 1): one over the twin planes, another near the top of the beveled surface, and a third on the unbeveled surface. In all three cases, the DLTS peak for titanium was not detected. There are two possible reasons for this. The area of the stripes is 200 mil$^2$ compared to the area of the standard DLTS dot, which is 706 mil$^2$. Thus, a factor of three in sensitivity is lost when the stripes are used for greater spatial resolution. The second reason is that the leakage current for the striped Schottky diodes was large, with 500 μA of current flowing at a reverse bias of 4 volts. This leakage current supplies a continuous flow of majority carriers past the traps in the depletion region. These majority carrier traps then tend to be filled by the leakage current rather than by the DLTS bias pulse, and this further degrades the sensitivity of the measurement. When the beveled samples were mounted on a TO-5 header and wire bonds were made from the stripes to the pins on the TO-5 package, the leakage currents were quite good, with a typical value of 20 μA at a reversed bias of 6 volts. The reason for the striped Schottky diodes degrading in leakage current is not known at this time. It is anticipated that leakage current will be limited to acceptable values for future Schottky striped diodes so that the titanium impurity will be more easily detected.
3.3.2 DLTS Measurements on Schottky Barrier Diodes Formed After Step Etching the Ti-Doped Web Crystal

In order to investigate the twin-plane-impurity interaction and because of some difficulty in the above experiment, an alternate approach was used in which titanium-doped web crystal was etched to various depths (0, 0.4, 1, 2, and 3 mils) to obtain a depth profile of Ti concentration. In this experiment conventional Ti-Au Schottky dots (30-mil diameter) were used as DTLS test devices and, because of the large area and low leakage current, there was more success in detecting Ti as a function of depth. It should be recognized that the DLTS concentration of Ti in a CZ-type material is only about 40% of the total grown-in Ti concentration in the bulk.\(^{(1)}\)

Figure 5 shows the depth profile of the electrically active Ti concentration. The data show a monotonic rise in the titanium deep-level concentration approaching the twin planes from the web surface. The twin planes are about 3 mils below the surface, suggesting that the grown-in impurities tend to pile up near the twin planes. In the case of Ti impurities, there is a difference of about a factor of five between the concentration near the twin planes and at the surface.

3.4 Electron-Beam-Induced Current (EBIC) Measurements to Investigate the Recombination Activity at the Twin Planes in Web Silicon

The first quarterly report\(^{(1)}\) showed laser-beam-induced current (LBIC) measurements on a couple of web crystals. LBIC measurements on those web crystals did not reveal any excess recombination activity at the twin planes, but one side of the twin plane showed more recombination than the other half. More LBIC measurements are being performed on baseline and Ti-contaminated web crystals to obtain further information about any twin plane recombination activity.

In this section a first attempt to look at the twin plane activity by electron-beam-induced current (EBIC) measurements. These measurements were performed at SERI on beveled web surface\(^{(2)}\) by fabricating 500 Å Al Schottky barriers on the beveled surface and 1000 Å Au ohmic contact on the back surface.
Figure 5. DLTS study of the interaction between grown-in titanium impurity and the twin planes in dendritic web silicon.
As shown in the optical photograph of Figure 2, part of the mechanically polished beveled surface was protected, while the other part was chemically etched to reveal the twin planes. EBIC scans were performed on both chemically etched and mechanically polished regions of a baseline web crystal, R461-4, and a Ti-contaminated web crystal, J167-1.3-TP3#8.

3.4.1 EBIC Measurements on Baseline Web Crystals

Figure 6 shows an EBIC picture of the baseline R461-4 web, where the chemically etched portion is in the dark area but the mechanically polished region can be seen clearly with the active twin planes. This EBIC picture also shows that a section of the twin plane is not as dark or electrically active as the rest of it. Also apparent is contrast due to some sort of a film and scratch-like marks on this sample. EBIC scans have been attempted through the section of the twin planes in the a) chemically etched region, b) mechanically polished region where the twin planes look dark, and c) mechanically polished region where the twin planes look relatively lighter.

Figure 7 shows the EBIC scan through the twin planes in the chemically etched region. A drop in the electron-beam-induced current is seen clearly at the two twin planes within this web crystal, indicating excess recombination at the twin planes compared to the rest of the bulk. The hysteresis in the current scan has something to do with the instrumentation since this is observed in all cases.

Figure 8 shows the EBIC on scan sample R461-4 through the section of polished region which is located ~400 μm away from the boundary of the etched and polished region. It is clear that the two twin planes look dark and show about 40% reduction in current, indicating considerable recombination at the twin planes. Recombination at the twin planes in this region is about a factor of three greater than the twin planes in the etched region (Figure 7).
Figure 6. Electron-beam-induced current (EBIC) picture of the beveled baseline web crystal R461-4. Twin planes can be seen on the polished beveled surface.
Figure 7. EBIC scan through the twin planes on the chemically etched region of the beveled web surface of baseline crystal R461-4 (I_b - 270 pA).
Figure 8. EBIC scan through the twin planes located on the polished beveled web surface of crystal R461-4. Scan is taken 400 μm away from the etched region ($I_b = 270$ pA).
Figure 9 shows the EBIC scan on sample R461-4 through the section of the polished region which is 700 μm from the bottom edge (Figure 6) and where the twin planes look somewhat lighter in contrast. Figure 9 shows that in this region one of two twin planes is not very electrically active, while the other twin plane shows the same amount of recombination as in Figure 8.

Thus it appears that although the twin planes are active, the recombination activity at the twin planes can vary considerably along the length of a web crystal.

3.4.2 EBIC Measurements on Titanium-Doped Web Crystal

Figure 10 shows an EBIC scan of the Ti-doped web crystal J167-1.3-TPE3#8, which was taken in the chemically etched region. The current scale magnification was the same as in the baseline crystal. In this region of the crystal some recombination activity is seen at the twin plane, but this activity is smaller than what was seen in the etched region of the baseline crystal (Figure 7).

Figure 11 shows an EBIC scan in the polished region of the Ti-doped crystal where somewhat more recombination at the twin planes is observed compared to what was seen in the etched region (Figure 10). The recombination activity in this figure also looks somewhat less than in the baseline samples of Figures 8 and 9.
Figure 9. EBIC scan through the twin planes located on the polished web surface of crystal R461-4. This scan was taken 700 μm away from the bottom edge ($I_b = 270$ pA).

4. PROGRAM STATUS

4.1 Present Status

The current milestone chart for this program is shown as Table 3. During this period we have:

- Studied the effect of stress on diffusion length in web crystals.
- Studied the twin-plane-impurity interaction by DLTS measurements on Ti-doped doped web crystal.
- Investigated the recombination activity at the twin planes by EBIC measurements.
- Fabricated some web solar cells.

4.2 Future Activity

Plans are to conduct more LBIC and EBIC measurements to understand the recombination activity of the twin planes and its impact on web cell performance. Heat treatment studies on web will continue with more emphasis on high-efficiency web cell fabrication.
