ABSTRACT

Ni-Mo alloys of compositions ranging from pure Ni to Ni-40 at % Mo were rapidly solidified by Chill Block Melt Spinning in vacuum and were examined by optical metallography, x-ray diffraction and transmission electron microscopy. Rapid solidification resulted in an extension of molybdenum solubility in nickel from 28 to 37.5 at %. A number of different phases and microstructures were seen at different depths (solidification conditions) from the quenched surface of the melt spun ribbons.

RAPIDLY SOLIDIFIED ALLOYS exhibit greatly refined microstructure, extended solid solubility, and metastable phase formation. The microstructures produced in these materials depend on alloy composition and local solidification parameters. In this paper the microstructural features observed in binary nickel-molybdenum alloys after Chill Block Melt Spinning are presented. This study forms the basis for investigation of other more complex Nickel-base alloy systems.

The equilibrium phase diagram for the Ni-Mo eutectic system (Ref. 1) is shown in Fig. 1. Under equilibrium the maximum solid solubility of Mo in Ni is 28.4 at %. $\beta$-phase (Ni$_3$Mo) has an equilibrium composition range from 51 to 53 at % Mo. The goal of this study was to determine the effect of rapid solidification on the microstructures of Ni-Mo alloys.

EXPERIMENTAL

The Ni-Mo ribbons used in this study were cast on a 4340 steel wheel by the free jet Chill Block Melt Spinning (CBMS) process at the NASA-Lewis Research Center. This facility is described in Ref. 2. Ni-Mo alloys of the compositions, Ni-0, 5, 17.5, 21, 27.5, 35, 37.5 and 40 at % Mo were used.

Figure 1. - Nickel-Molybdenum phase diagram. X's indicate casting temperatures and compositions.

All ribbons were examined by x-ray diffraction using Cu-Kα radiation on both sides (wheel and free) of the ribbons. In this paper the quenched side of the ribbon will be referred to as the wheel side, and the side away from the wheel will be referred to as the free side. Cross sections of the samples etched with Marble's Reagent were examined by optical metallography. Transmission electron microscopy (TEM) was carried out for three alloys, namely Ni-27.5 at % Mo (hypoeutectic), Ni-35 at % Mo (eutectic) and 37.5 at % Mo (hypereutectic). Three regions of the melt-spun ribbons, namely wheel side, midsection and the free side were examined. Of these three sections the wheel side represents the fastest quench region. Samples were electropolished by a twin jet method using an ethanol (45 vol %), butyl cellosolve (45 vol %) and perchloric acid (10 vol %) electrolyte cooled to about 0 °C. For examination of
near-wheel and near-free sides, these surfaces were protected by lacquer and the ribbon was thinned only from the other side.

RESULTS AND DISCUSSIONS

Ribbons cast for this search were approximately 40 μm thick, 2.5 mm wide and up to 15 in in length. The castability of pure nickel was so poor that no single layer ribbons of pure nickel were obtained. In general ribbon length and castability increased with increasing molybdenum content.

X-RAY DIFFRACTION - The Ni-fcc phase (γ) was identified in all compositions. The lattice parameter of this phase increased with increasing Mo content up to about 37.5 at % Mo. The lattice parameter data for the rapidly solidified ribbons are compared to conventionally cast samples in Fig. 2. For the conventionally cast material a linear increase in lattice parameter with the increasing molybdenum content is observed up to about 27.5 at % Mo. The lattice parameter remains constant beyond this molybdenum content, as would be expected from the Ni-Mo phase diagram, Fig. 1.

The extended solid solubility of the rapidly solidified ribbons up to about 37.5 at % Mo is illustrated by the extended straight line relationship between lattice parameter and molybdenum content of the γ phase in this figure. The lattice parameter data in this figure compare well with the values reported for Ni-Mo alloys of the composition 0 to 20 at % Mo (Refs. 3 and 4). This observation of extended solid solubility by rapid solidification is further augmented through TEM analysis. In addition to the extended solid solubility of fcc Ni-phase (γ), indications of B-NiMo (orthorhombic) were found near the wheel side of ribbons from Ni-35 at % Mo and Ni-37.5 at % Mo alloys. These observations were also found to be consistent with the TEM analysis, as will be shown in a latter section.

Figure 2. - Lattice parameter of γ as a function of composition for conventionally cast and rapidly solidified alloys.

OPTICAL METALLOGRAPHY - Metallographic analyses showed the following results: Multiple layer pure Ni ribbons showed very large grains. Alloys of 5 to 28 at % Mo, those in the γ solubility range (Fig. 3), showed cellular/dendritic growth throughout the thickness of the ribbon. The γ grain size was observed to decrease with increasing molybdenum content. Three zones were observed in alloys of higher Mo, >28 at %, content. A featureless zone appeared closest to the wheel (Figs. 3 (d) to (f)). Directly adjacent and separated by a boundary was a planar from growth zone. As the planar front zone broke down, cellular/dendritic grains formed. The amount of the featureless zone increased with increasing Mo content.

TRANSMISSION ELECTRON MICROSCOPY - The results of the TEM analysis of the three alloys studied in detail are summarized in Table I. Figures 4 to 9 show the corresponding typical microstructures. All three alloys showed significant effects of rapid quenching. One of the unique microstructural features was that of supersaturated and faulted Ni-fcc (γ) grains. This was the only microstructure found in the hypoeutectic alloy (27.5 at % Mo) in the near wheel region. Here, as shown in Fig. 4, supersaturated γ-fcc grains were found to nucleate along a line (presumably grinding marks on the quenching wheel) and grow parallel to the wheel surface (region A in Fig. 4). In addition, in several locations, Ni grains appear to have nucleated at a point on the wheel surface and grown radially, (region B in Fig. 4) normal to the wheel surface resulting in grain structures like flower petals. On closer examination of the individual γ grains it was found that most of the grains contained finely spaced linear features (Fig. 5). These features are due to planar faults, which could be considered as micro-twinned platelets of about 15 Å thickness. Detailed diffraction analysis of these are described elsewhere (Ref. 5). These faulted γ grains were also found in the eutectic alloy (35 at % Mo) near the wheel-side and in the hypereutectic alloy (37.5 at % Mo) in the mid section. Figure 5 is typical of the faulted γ grains found in the alloys.

The eutectic and hypereutectic alloys showed a fine NiMo microcrystalline region near the wheel side of the ribbon (Fig. 6). This is believed to have formed by crystallization of an amorphous phase which initially formed during quenching. The hypereutectic alloy showed an amorphous region surrounded by α-NiMo grains (Fig. 7). In-situ heating of the amorphous regions in the TEM produced a distribution of fine microcrystallites similar to the ones shown in Fig. 6.

Figure 4. - Bright field TEM micrograph showing $\gamma$-Ni (fcc) grains in hypoeutectic alloy in the near wheel side region of the ribbon.

Figure 5. - Typical faulted $\gamma$-fcc Ni grains in hypoeutectic (near-wheel side), eutectic (near-wheel side) and hypereutectic (midsection) alloy ribbons.

Figure 6. - Typical microcrystalline $\beta$-NiMo regions seen in eutectic (near wheel side) and hypereutectic (near wheel side) alloy ribbons.

Figure 7. - Amorphous phase (region A) surrounded by $\beta$-NiMo grains in the hypereutectic alloy ribbon (near wheel side).
Another unique microstructure is the faulted θ-NiMo grains found in the midsections of hypereutectic (37.5 at % Mo) ribbons. The fault contrast is seen both in the bright field and dark field images shown in Fig. 8.

Dendritic γ cells were found in the midsection and free surface region of all three alloys. The typical cellular appearance as shown in Fig. 9 was the same for all three alloys. The fraction of the interdendritic eutectic found in the γ dendrites was greater in the near free surface regions than other part of the ribbon. It also increased with the increasing molybdenum content of the alloy.

CONCLUSIONS

The following conclusions were made from this study of rapidly solidified Ni-Mo alloy ribbons:

(1) Molybdenum solid solubility in fcc Ni (γ) was extended from about 28 to 37.5 at % Mo by rapid solidification. It resulted in the formation of γ grains with planar-faults.

(2) Alloys with molybdenum content at and above the eutectic composition (> 35 at % Mo) showed an amorphous phase as
a result of rapid solidification. Some of this amorphous region crystallized into very fine microcrystallites.

(3) The hypereutectic composition alloy formed very large, faulted, orthorhombic $\beta$-NiMo grains, even at moderate cooling rates (mid sections of ribbons).

(4) In the slow cooled regions all the alloys showed the cellular/dendritic growth of $\gamma$ phase with $\gamma/\beta$ interdendritic eutectic.

ACKNOWLEDGMENT

Appreciation is expressed to R.W. Jech, T.J. Moore and N.W. Orth for preparing the melt-spun ribbons. Special thanks are due to Dr. Hugh R. Gray for his keen interest and continuous encouragement.
