ABSTRACT

Cross sections for the production of secondaries with large transverse momentum can become comparable to the total cross section in the TeV energy range. We argue that the onset of this effect is observed at sub-TeV energies via (i) an increase of the rapidity distribution near \( y = 0 \), (ii) an increase of \(<p_T>\) with energy and, most directly, via (iii) a correlation between \(<p_T>\) and multiplicity. If indeed scaling violations are associated with the hard scattering of partons, then scaling violations are largely confined to the central region and have little effect on cosmic ray data which are sensitive to the forward fragmentation region.

Recent pp-collider experiments confirmed the observation by the Brazil-Japan emulsion group that the average transverse momentum of secondaries is larger in events with high multiplicity,\(^1\) see Fig. 1. QCD allows for a straightforward interpretation\(^1\) of this observation: large \( p_T \) results from hard scattering of partons, and hard scattering is accompanied by abundant gluon radiation resulting in an increased multiplicity. This effect is most dramatically observed in hard quark + antiquark + weak boson events where the hadronic activity accompanying \( W, Z \) is larger\(^2\) than that in average minimum bias events despite the fact that roughly 1/5 of the c.m. energy \( \sqrt{s} = 0.54 \text{ TeV} \) is taken away by the \( W \) or \( Z \) mass. This interpretation of the \( <p_T> \)-multiplicity correlation received further confirmation by the recent observation\(^3\) that high multiplicity events indeed show jet-like final state structure. A large fraction of them contained at least one identified jet with \( p_T \geq 5 \text{ GeV} \). Although the QCD origin of large \( p_T \) jets has been quantitatively verified we are here discussing events where the "large" \( p_T \) is not much larger than \( <p_T> \) and perturbative calculations are difficult. We discuss this next.

Perturbative calculations of jet cross sections are made possible by the fact that hadrons interact over a distance scale \( O(1/p_T) \) which is small. The hadrons interact via a single quark or gluon in each hadron. When \( p_T \) becomes small many relative soft constituents are stacked in the interacting hadrons and therefore multiple parton-parton interactions become likely in a single hadron-hadron collision. Perturbation theory breaks down; e.g. for the SSC energy \( \sqrt{s} = 40 \text{ TeV} \) we estimate following Ref. 4 that the cross section for double parton-parton interactions is \( 100 \sim 200 \text{ mb} \) for \( p_T \geq 6 \text{ GeV} \). This is roughly...
equal to the conventional single hard scattering cross section for $p_T \geq 6 \text{ GeV}$ as we will see further on. Conversely one might actually hope that naive perturbation theory yields reliable results for $p_T$-values as low as $5 - 10 \text{ GeV}$ which corresponds to $x (= p_T/\sqrt{s}) \approx 10^{-5}$ at $\sqrt{s} = 40 \text{ TeV}$.

Using perturbative QCD jet calculations down to $x \approx 10^{-3}$ we have made a toy model of hadronic interactions at all energies and all $p_T$. The basic idea is to integrate the perturbative QCD expressions for hard scattering of constituents down to an energy-dependent $p_T \min$ defined by

$$\sigma_{\text{tot}} = \sigma_0 + \sigma_{\text{jet}} (p_T \min),$$

where

$$\sigma_{\text{jet}}(p_T \min) = \int \int \int F(x_1)F(x_2)\sigma(\theta).$$

$F(x_i)$ are the probabilities for finding constituents with fractional momenta $x_i$ in the incident hadrons and $\sigma(\theta)$ is the elementary cross section for scattering of constituents to angle $\theta$ defined in the parton-parton c.m. system. Unlike the calculation of Ding, et al., we have no cutoff in $\theta$ except that required by $p_T > p_T \min$. The factorization displayed in Eq. (2) is an approximate result suitable for practical calculations. $\sigma_0$ represents the soft hadronic cross section and further results will depend on assumptions regarding its magnitude and energy dependence. For illustration we assume $\sigma_0 = 38 \text{ mb}$ at all energies. Table I shows values of $\sigma_{\text{jet}}, p_T \min$ and mean values of Feynman $x$ and rapidity of the scattered jet obtained from Eqs. (1, 2). For details of the calculation see Ref. 1. The values of $p_T \min$ have been adjusted so that Eq. (1) reproduces the total cross section data shown in Fig. 2. Our calculation also reproduces the $p_T$-distribution measured at the $pp$ collider, see Fig. 3.

Because of the large cross sections involved, such semihard processes can be expected to produce dramatic effects at high energy. Figure 4 illustrates the expected energy dependence of the rapidity distribution at various energies of interest. We have assumed that beam fragments in hard collisions produce rapidity distributions of secondary pions as in soft collisions, with two charged particles per unit of rapidity. The scattered jets are assumed to produce rapidity distributions of the same shape as beam fragments at the kinematic limits, and also with an asymptotic density of two charged particles per unit of rapidity. In the absence of significant scaling violation effects in the fragmentation functions, we would predict an asymptotic rapidity density of four charged particles.

By energy conservation one expects a violation of scaling in the fragmentation region as the central component grows with energy. The magnitude of this effect can be estimated from the values of $<x_{\text{jet}}>$ tabulated above. At high energies, where semihard scattering events represent a significant fraction of the cross section, $<x_{\text{jet}}> \approx 0.05$ so we expect fragmentation region scaling violation only at the level of 5%. This is a smaller effect than suggested in Ref. 5.
We therefore conclude that if the association between hard scattering and increasing cross section described here is qualitatively correct, then scaling violations should have little effect on the behavior of the electromagnetic component of cosmic-ray cascades because these depend primarily on the fragmentation region. In particular, use of scaling-type models to interpret the Fly's Eye experiment should be essentially correct. A non-trivial result of the calculation that increases our confidence in the correctness of the association between growing cross section and hard scattering is represented by the last column of Table I. The jet rapidities that come out of the QCD calculation are such that the excess rapidity density from the scattered jets joins smoothly onto the underlying rapidity plateau from beam fragments. The Gaussian-type rapidity distribution observed at \( \sqrt{s} = 540 \text{ GeV} \) is thus naturally reproduced.

FIGURE 1. Increase of $\langle p_T \rangle$ associated with increasing multiplicity.

FIGURE 2. The increasing cross section associated with jets of moderate transverse momentum.

FIGURE 3. Two-component description of the charged particle transverse momentum distribution. The low-$p_T$ component is described by an exponential fall-off with $p_T > 340$ MeV. The "high"-$p_T$ component corresponds to hadrons which are the fragments of parton jets with $p_T > p_T \max$ chosen as in Table I. Data from the UA1 experiment.

FIGURE 4. Sketch of the two-component rapidity distribution corresponding to the two-component total cross section shown in Fig. 2. At each energy the rapidity distribution consists of a plateau on which is superimposed the excess of hadrons near $y = 0$ due to fragmentation of the scattered jets. Rapidity of the scattered jets are indicated by arrows. The excess is cross-hatched for $\sqrt{s} = 0.54$ TeV.
