ULTRA HIGH ENERGY EVENTS IN ECHOS SERIES AND
PRIMARY ENERGY SPECTRUM
Capdevielle J.N., Lab. Phys. Théorique, Bordeaux, rue du Solarium, 33170 Gradignan, France

1. ECHOS series. EMULSION chambers with X-ray film are boarded on the supersonic Concorde Air France liner from October 1978. Since, 6 chambers have been exposed at the highest altitude (about 16Km). The different flights of the French-Japanese collaboration (often quoted as Concorde Collaboration) have been scheduled on Atlantic between Paris and New York as listed in table 1. (ECHOS-Emulsion Chamber On Supersonic).

Table 1

A description of the different chambers and sensitive materials can be found in previous reports (1,2,3) as well as the collection of remarkable events in ECHOS1,2,3 between 10⁻⁶-10³ GeV; we examine hereafter those events, jets, stratospheric ray family in view to point out some signature of phase transition quark gluon plasma and try from a general review of the data of flying experiments (Concorde, JAL cargo jets, JACEE) to situate the tendency of primary cosmic ray spectrum.

2. Correlation rapidity density-<pₜ> . A survey of ISR and P-P data has been taken from Hagedorn's compilation and joined to our data and analysis of cosmic ray jets (2) on Fig.1. The accelerator data suggested a clear increase of <pₜ> with rapidity density dn/dy and also that <pₜ> levels off at highest densities (16). The total pₜ distribution has been derived from well collimated and localized jets in emulsion chambers like JF1af1 In Concorde(2), Texas Lone Star In stack, C-C and Ca-C collisions in JACEE(5,6) or in Chacaltaya experiment(7). Admitting that <pₜ> is the same for nucleon-nucleus collision, we can extend the behaviour of <pₜ> versus dn/dy by one order of magnitude(fig.1). Inside the experimental errors, the prediction of Barshay

\[
\langle pₜ \rangle = 0.32 \exp \left[ \frac{1}{7} \ln(1 + \frac{3}{\exp(-0.519 \frac{\text{d}y}{\text{d}y})}) \right] \frac{\ln(3 - \exp(0.516 \frac{\text{d}y}{\text{d}y}))}{\exp(-0.0516 \frac{\text{d}y}{\text{d}y})}
\]

looks in better agreement than the hybrid model containing thermodynamic coupled with collective motions, which links phase transition and <pₜ> flattening.(4)

It was advanced that the bumps occurring in pseudo-rapidity distribution could also be a signature of transition to quark-gluon plasma. We have carried out a Monte-Carlo simulation of 1500 p-Aluminium collisions for specific comparison with our typical event JFaf1 produced in Concorde cabin wall. The multicluster phenomenological model (MPM) has been used to extrapolate the collider data (see HE4.1-9,10), assuming simultaneous rise in Lns of height and width of plateau, random production of small clusters decaying with Gaussian distribution and finally inclination of plateau for nucleon-nucleus collision. The average number $\langle \psi \rangle$ of successive collisions in Al target has been taken as 2 at low energy.

The pseudo-rapidity distribution plotted on fig.2 for $E = 2.10^6$ GeV includes all the possible fluctuations in multiplicity and inelasticity for p-Al collisions (where $\bar{n} = 73$). If the discrepancy of the left part can be easily explained by the $\gamma$-ray threshold of 100 GeV, the simulation cannot explain the large number of $\gamma$ rays emitted (about 50%) at very high rapidity. Subtracting the forward part of simulated from experimental distribution, we obtain superposition of two components, one being consistent with the extrapolation of accelerator data (containing near 80 $\gamma$'s), also for $n$ estimated to 45 in JFaf1, and one additive component characterized by a narrow peak with Gaussian distribution centered at 2.7 unit of rapidity in CMS with FW{$\gamma$}M near 1 unit.

This could be the rapidity signature of an explosive decay of phase transition fireball after compression of the projectile fragmentation fireball in the target (the target fragmentation fireball cannot be seen with $\gamma$ rays in emulsion chamber). Such procedure repeated with $E_o = 10^6$ GeV lead to similar results even more pronounced.

5. Primary energy spectrum.

Using the relations previously developed between $E, \Sigma E, r, \frac{E}{R}$ for stratospheric $\gamma$ ray family with SBM model by Monte-Carlo simulation, we make a first attempt (now repeated with MPM) to estimate the integral primary spectrum from the primary energy $E$ of ultra high energy jets in our Concorde and JAL cargo data (table 2,3) in "average conditions".

Table 2. Concorde data.
**Fig. 2**

Concorde event

**Fig. 3**

\[ E_p^{1.5} I \left( \frac{m^{-2} \cdot s^{-1} \cdot sr^{-1} \cdot eV^{1.5}}{} \right) \]
Taking into account the exposure period and the area of the different chambers, we estimate the integral hadron energy spectrum at $260 \text{ G-cm}^{-2}$ and $105 \text{ g-cm}^{-2}$ and converted those spectra in total primary spectrum assuming $\Lambda = 105 \text{ g-cm}^{-2}$ for hadron absorption length in air. The situation obtained, together with JACEE data is shown on fig. 3. The total 18 events (6 Concorde+6 JACEE+6 JAL) suggests a tendency for a bump in primary spectrum near $10^{-6}$-10 GeV. Furthermore, those intensities are close from those obtained by EAS near maximum (9).

6. Conclusion. The compilation of ultra high energy jets suggests at present the existence of a bump in primary energy spectrum (with the standard concept of high energy collisions). The pseudo rapidity distribution exhibits some typical anomalies, more than the $\langle p_T \rangle$ behaviour, which are, may be, the fingerprints of quark gluon plasma transition. The next results of ECHOS V will be in both cases determinant to confirm those tendencies, as well as an important effort of the cosmic ray community to develop in that sense flying emulsion chamber experiment.
