(602) 626-1306
Introduction

As a biological tissue, muscle adapts to the demands of usage. One traditional way of assessing the extent of this adaptation has been to examine the effects of an altered-activity protocol on the physiological properties of muscles. However, in order to accurately interpret the changes associated with an activity pattern, it is necessary to employ an appropriate control model. There exists a substantial literature which reports altered-use effects by comparing experimental observations with those from animals raised in small laboratory cages (e.g., Steffen and Musacchia, 1984; Templeton, Padalino, Manton, Glasberg, Silver, Silver, DeMartino, Le Coney, Klug, Hagler, and Sutko, 1984). Some evidence suggests that small-cage-reared animals actually represent a model of reduced use. For example, laboratory animals subjected to limited physical activity have shown resistance to insulin-induced glucose uptake which can be altered by exercise training (Mondon, Dolkas, and Reaven, 1983).

This project concerned the basic mechanisms underlying muscle atrophy. Specifically, the project addressed the issue of the appropriateness of rats raised in conventional-sized cages as experimental models to examine this phenomenon. The project hypothesis was that rats raised in small cages are inappropriate models for the study of muscle atrophy. The experimental protocol involved: (1) raising two populations of rats, one group in conventional (small)-sized cages and the other group in a much larger (133x) cage, from weanling age (21 days) through to young adulthood (125 days); (2) comparison of size- and force-related characteristics of selected test muscles in an acute terminal paradigm.
Methods

Housing

Male and female Sprague-Dawley rats were raised from weanling age (21 days) for 89-156 days ($\bar{X} \pm = 141 \pm 17$) in either of two sized cages. The small-cage animals were raised in conventional small laboratory cages (20 cm x 47 cm x 25 cm, 3-5/cage). The large cage provided approximately 133x more usable surface area (floor and 4 cage walls) for the animals and included climbing structures and exercise wheels. The activity of neither group of animals was monitored. The rats were provided with food and water ad libitum.

Two batches of animals were studied. In the first group (Batch 1), the males were raised and studied first; the females were procured subsequently. In the second group (Batch 2), the males and females were obtained at the same time and raised concurrently although in separate cages. By chance, but of subsequent relevance, the two batches were raised in two different buildings. All other details of the experiments were identical for the two groups.

Preparation

Terminal experiments were performed with the rats under halothane anesthesia. The anesthesia was delivered via a face mask, initially at a concentration of 4% and flow rate of 5 L/min. Following intubation of the trachea, anesthesia was maintained at a pain-free level for the extent of the experiment at halothane concentration of 1-2% as needed in a 50% N₂O-50% O₂ mixture with a total flow of 0.6 L/min. Respiration rate (90-120 breaths/min), percent expired CO₂, and rectal temperature (35-37°C) were monitored and adjusted to maintain homeostasis throughout the experiment. The left soleus and extensor digitorum longus muscles were surgically isolated by removing overlying and adjacent musculature. All branches of the sciatic nerve were transected near the hip, and those branches innervating soleus (soleus muscle nerve) and extensor digitorum longus (lateral peroneal nerve) were isolated for subsequent stimulation.
The animal was secured in a rigid frame, and the left hindlimb was clamped with the knee at an angle of about 120 degrees. The test muscles were maintained in vivo in a paraffin oil-filled bath at a temperature of 36 ± 1°C.

Recording Procedures

The test muscles were activated with a monopolar, stainless-steel, hooked wire electrode (referred to a similar electrode in an adjacent denervated muscle) by supramaximal cathodal stimulation (3-5x threshold, 0.1 ms square waves) of their nerves. The force elicited by such activation was measured by a force transducer that was attached to the tendon of the muscle by a low-compliance (<0.03 μm/N/cm) dacron line (X ± SD length = 15.6 ± 1.3 cm). The whole-muscle electromyogram (e.m.g.) was measured with a spring-mounted, flexible, stainless-steel, intramuscular electrode (18 mm long, 120 μm thick, 40 μm tip) that was thrust into the distal one-third of the muscle, perpendicular to the long axis of the muscle. The intramuscular electrode was referred to a similar electrode placed in an adjacent denervated muscle.

Preliminary experiments indicated that the optimum muscle length for peak twitch force, for both soleus and extensor digitorum longus, was achieved when the muscle was stretched to exert a passive force of 0.15 N. Throughout the test, the length of the test muscle was altered to sustain a passive force of 0.15 N. No attempt was made to determine length-tension relationships during the present experiments for fear of fatiguing the muscle.

Experimental Protocol

Each muscle was activated separately with the following 5-step protocol: (1) 32 twitches at 0.5 Hz were elicited by stimulation of the nerve to both evaluate and circumscribe the effects of treppe; (2) a single tetanus of 100 Hz for 500 ms to determine tetanic force (this stimulation elicited approximate peak force in soleus, but stimulation rates of 250 Hz are required to elicit peak force in extensor digitorum longus (Close, 1964); (3) a 6-min application of a standardized stimulus regimen (Burke, Levine, Tsairis,
and Zajac, 1973) which involved repetitive intermittent stimulation (40 Hz) of the nerve with trains of 13 stimuli, each train lasting 330 ms and occurring once each second to evaluate fatigability; (4) 8 twitches at 0.5 Hz to evaluate the effects of the fatigue test on twitch force; and (5) two 100 Hz tetani, 10 s apart to evaluate the effects of the fatigue test on tetanic force. Approximately five seconds elapsed between consecutive phases of the protocol. The stimulus protocol was controlled with a small laboratory computer. Data were recorded on-line with the computer and on FM magnetic tape for a more detailed off-line analysis.

The animal was then terminated with an intracardiac injection of magnesium sulfate. The two test muscles were removed, frozen in isopentane cooled to its melting point, and stored at -70°C for subsequent histochemical analysis.

Data Analysis

Age and body weight were recorded for each rat at the time of the physiological experiment.

Physiological. The issues addressed in the first full-length paper (see Results) concern the affects of cage-size and gender on the force production capacity of the two test muscles as revealed by the above stimulation protocol. Each twitch was characterized by determining the peak force (N), time-to-peak force (ms), and half-relaxation time (ms). The peak force (N) was determined for each of the three 100 Hz tetani. For the 360 trains of the fatigue test, peak force, time-to-peak force, and two relaxation times (i.e., time for decay of force from 90% to 50% and from 50% to 20%) were determined. The Fatigue Index was defined as the peak force of the 360th train of the fatigue test expressed as a percent of the peak force of the initial train.

The e.m.g., which comprised the action potentials associated with each train of stimuli, was represented by the averaged waveform, and quantification was based on this average waveform. Measurements on the average waveform included four measures of amplitude, four of duration, and area, each of which reveals different features of muscle
action-potential generation, and propagation. The e.m.g. measurements are defined in the following manner: (1) absolute peak-to-peak amplitude, the magnitude of the difference (mV) between the absolute maximum and minimum; (2) first peak-to-peak amplitude, and magnitude of the difference (mV) between the maximum of the initial positive phase and the minimum of the subsequent negative phase; (3) mean amplitude, the ratio (mV) of area to waveform duration; (4) "mean" amplitude, the ratio (mV) of area to peak-to-peak duration; (5) baseline-to-baseline duration, the time (ms) from the beginning to the end of the waveform where the beginning and end are defined as a 5% deviation of the waveform from the preceding and succeeding baselines; (6) peak-to-peak duration, the time (ms) between the maximum of the initial positive phase and the minimum of the subsequent negative phase; (7) peak-to-peak rate, the average rate (mV/ms) of change between the initial positive-phase maximum and the negative-phase minimum; (8) normalized peak-to-peak rate, the reciprocal (1/ms) of peak-to-peak duration; (9) area, the integral (mV·ms) of the e.m.g. waveform where the beginning and end are defined for the measurement of baseline-to-baseline duration.

**Histochemical.** Serial frozen sections (10 µm in thickness) from the middle one-third of the muscle belly were cut, with alternate sections stained for succinate dehydrogenase (SDH) according to a modification of the methods of Pette and colleagues (Pette, Wasmund, and Wimmer, 1981; Pette, 1981) or myosin ATPase (pH 9.3 and 4.3) according to the methods of Guth and Samaha (1972). The fiber-type composition of the muscles was determined by classifying approximately 300 fibers per muscle (range = 265-368) located in the more central region of the cross section. Fibers were classified according to the nomenclature of Peter, Barnard, Edgerton, Gillespie, and Stempel (1972): SO (slow, oxidative) fibers stained light for myosin ATPase (using the alkaline preincubation) and intermediate to dark for SDH; FOG (fast-contracting, oxidative, and glycolytic) fibers stained dark for both ATPase and SDH; and FG (fast-contracting, glycolytic) fibers stained dark for ATPase but light for SDH. The relative percent
contribution of each fiber type was determined by dividing the number of fibers of a given type by the total number of fibers counted in that muscle and then multiplying by 100. These values represent the average of results from two independent observers. In addition, a subset of these fibers (70-100 fibers/muscle) were characterized in more detail through the use of a computer-assisted image processing system (made available by Dr. V.R. Edgerton, Department of Kinesiology, UCLA). This involved a microphotometric analysis of SDH activity according to the methods of Castleman, Chui, Martin, and Edgerton (1984) and determination of cross-sectional area.

To test for significant effects due to cage-size, gender, or batch, a multiple analysis of variance was used. A Newmann-Keuls comparison was used for post-hoc analysis with the critical value for significance of p <0.05. Statistical differences in fatigability were assessed with single and multiple linear regression analyses and with an analysis of variances.
Results

The experimental results accumulated during this three-year project have been reported to the scientific community in two formats: (1) as ten abstracts presented at meetings of national and international societies; and (2) as five full-length papers. For this report, the abstract citations are listed, and the abstracts are attached at the end of the report; and summary outlines of the full-length papers are provided. Complete manuscripts can be provided if it is deemed desirable.

Abstracts

Papers

The results and conclusions of the project are described fully in the following five papers. Drafts of these manuscripts are available upon request.

1. "Effects of cage size and gender on the properties of developing rat hindlimb muscle."

   a. Male and female Sprague-Dawley rats were raised in separate groups from weanling age in either of two cage sizes. In terminal experiments, cage-size and gender effects were assessed with measures of size, force, contractile speed, fatigability, muscle fiber-type composition, and oxidative-enzyme activity for two test muscles, soleus and extensor digitorum longus.

   b. In general, cage size did not affect any of these measures.

   c. Similarly, apart from well-documented gender differences (e.g., muscle : body mass, twitch : tetanus force) the effect of cage size was similar for both male and female rats. There was, however, a greater variability (coefficient of variation) in many of the test measures exhibited by the female rats.
d. One group of large-cage male animals did demonstrate a significant effect of cage size relative to control animals. However, this observation probably reflected an environment effect due to the physical characteristics of the environment in which that particular cage was located.

e. It appears that rats of either gender raised in conventional laboratory cages represent an appropriate experimental model for altered-use paradigms.

2. "Fatigability of rat hindlimb muscle: E.m.g.-force relationship."

a. An experimental protocol designed to assess fatigability in motor units (Burke, Levine, Tsairis, and Zajac, 1973) has been applied to the whole-muscles of anesthetized adult rats and the electromyogram (e.m.g.)-force relationship monitored over the course of the test.

b. The animals were raised in either a small or a large cage. As a result, both test muscles (soleus and extensor digitorum longus) exhibited a wide range of fatigability, which was defined as the decline in isometric peak force at 6 min, such that the data for each test muscle were separated into groups of high, intermediate, and low fatigability.

c. The e.m.g. was quantified with four measures of amplitude, four duration variables, and one interaction term (area). Correlation analyses indicated that the e.m.g. was adequately represented by one measure of amplitude (absolute amplitude), one of duration (peak-to-peak duration), and area.

d. The e.m.g.-force relationships for soleus varied markedly between the three fatigability groups. In contrast, all three extensor digitorum longus groups displayed qualitatively similar e.m.g.-force relationships over the course of the test.

e. Multiple regression analyses indicated that the e.m.g. parameters were able to predict peak force better for extensor digitorum longus than for soleus.
Furthermore, for both test muscles the prediction was best for the high fatigability group.

f. The associations between e.m.g. and force appeared to depend upon the measure used to quantify the e.m.g., the fiber-type composition of the test muscle, and the degree of fatigability exhibited by the muscle.

3. "Fatigability of rat hindlimb muscle: Coexistence of potentiation and force decline."
   a. An experimental protocol designed to assess fatigability in motor units (Burke, Levine, Tsairis, and Zajac, 1973) has been applied to whole muscle of anesthetized adult rats in order to study the effects of the test on the magnitude of twitch potentiation.
   b. The animals were raised in either a small or large cage. As a result, both test muscles (soleus and extensor digitorum longus) exhibited a wide range of fatigability, defined as the decline in isometric force observed at 6 min, and twitch potentiation, defined as the increase in twitch force observed after, compared to before, the fatigue test.
   c. In the soleus, 57% (42/74) of the muscles exhibited fatigue (i.e., force at 6 min less than 100% of initial force); of these, 14% (6/42) also exhibited potentiated postfatigue-test twitch force. In contrast, all (68/68) extensor digitorum longus muscles exhibited fatigue, and of these, 46% (31/68) also showed twitch potentiation.
   d. In both test muscles, an inverse linear relationship was found between the degree of twitch potentiation and the magnitude of fatigue exhibited, although the relationship in soleus was different from that in extensor digitorum longus.
   e. Some recovery of the whole-muscle e.m.g. was evident between the end of the fatigue test and the first posttest twitch. However, there was no correlation between the degree of twitch force potentiation and any of the e.m.g. parameters studied.
f. The simultaneous occurrence of whole-muscle fatigue and twitch potentiation in some muscles suggests that the mechanisms underlying these two phenomena affect different sites within the muscle, but the linear relationship suggests that they are not totally independent of one another.

4. "A comparison of qualitative and quantitative histochemical classification of muscle fiber types."
   a. The metabolic heterogeneity seen within a given muscle fiber type, first described for fibers classified on the basis of myosin ATPase staining, has been confirmed for fibers classified according to the SO-FOG-FG scheme of Peter, Barnard, Edgerton, Gillespie, and Stempel (1972). All 3 fiber types exhibited a broad range of succinate dehydrogenase activities as determined by quantitative histochemical techniques.
   b. In soleus, mean SDH activity for FOG fibers was significantly greater than that for SO fibers; whereas in extensor digitorum longus, mean values for SO and FOG fibers were identical to each other but significantly greater than that for FG fibers.
   c. There was considerable overlap of SDH activities for the 3 fiber types precluding differentiation of fiber type based strictly upon oxidative potential. This, combined with the similarity of values for soleus SO fibers and extensor digitorum longus FG fibers, suggests that the differences in fatigability which characterize these 3 fiber types are not due solely to the differences in their oxidative capacity.

5. "The effects of disuse on skeletal muscle."
   This final manuscript is a review which is organized in the following manner:
   Effects of Reductions in Muscle Usage
     Models of Reduced Use
Neural Alterations
Muscular Alterations
Effects on Muscle Properties
Morphological Changes
Macroscopic
Ultrastructural
Histochemical and Biochemical Changes
Metabolic Capacity
Myofibrillar Components
Additional Biochemical Alterations
Fiber-Type-Distribution

WEIGHTLESSNESS HYPOKINESIA: SIGNIFICANCE OF MOTOR UNIT STUDIES

Douglas G. Stuart and Roger M. Enoka*

Departments of Physiology and Physical Education*,
University of Arizona, Tucson, AZ 85724

ABSTRACT

In preliminary experiments, we found that medial gastrocnemius (MG) motor units in cage-reared rats were unusually sensitive to fatigue, a test for which is required to distinguish between FF- and FR-unit types. This observation prompted an analysis of whole-muscle fatigue. It revealed an impairment of the electrochemical process of neuronal excitation-contraction coupling at one or several sites between motor axons and the contractile machinery. (Supported by NASA Grant NAGW-338).

INTRODUCTION

Following preliminary experiments (see Abstract), we undertook an analysis of whole-muscle fatigue in the MG of cage-reared rats, together with an estimation of the fatigability characteristics of MG in a theoretical "noncaged-reared" rat model, assuming the theoretical muscle would have unit properties like those found in hindlimb muscles of noncage-reared cats (3,5,6).

METHODS

We used 500 g male and female 100-day old Sprague-Dawley rats, who had spent their life in 46-49 x 25-28 x 20 cm cages (4-7/cage). Such confinement is typical for commercially bought rats. Under pentobarbital sodium anesthesia (30-70 mg/Kg, I.P.), MG was prepared for force and EMG measurements (3,5,6).

RESULTS

Experiments. Fig. 1 shows force and EMG responses of MG (N = 7). Note three points:

1. Before the fatigue test, the disparity between force output for direct and nerve stimulation was greater than considered normal (2,4).

2. The fatigue test produced more substantial reductions in force and EMG than anticipated (3,5). Unfortunately, there are no data comparable to Fig. 1 for noncage-reared rats. However, Table 1 (lines 8, 11) suggests that EMG (force) reduction would be 23% (62%) in the theoretical MG as compared to 66% (79%) in our test MG (Fig. 1).

3. Intermittent and abrupt changes in EMG amplitude were a feature of each stimulus train of the fatigue test, even before force declined.

Estimations. Three assumptions in the Table 1 estimations require explanation:

1. Values for the relative distribution of the different fiber types (Table 1, line 1) are only available for cage-reared rats. They should not differ markedly in noncage-reared rats (3).

2. The assumption that the amplitude of the EMG co-varies with muscle-fiber diameter (3/2) is based on measurements made on "in-continuity" mammalian nerve axons (8).

3. At first glance, the assumption might seem far-fetched that relative (inter-unit) features of motor-unit anatomy (Table 1, lines 1-4), force development (line 9) and fatigability (lines 7, 10) are similar for rat MG and cat tibialis anterior (TP; footnotes 3-4). However, the specific tension (force/cross-section) of muscle tissue is quite similar across species (6), as are presumably the EMG:force relationships.

DISCUSSION

Orderly motor-unit recruitment (3) should prevail in cage-reared rats with cumulative activation (recruitment) of progressively more forceful units for progressively stronger contractions. As a result, it is likely that the FF units of cage-reared rats are used to less extent than the less forceful FR and S units (3,6). On this basis, we propose that the impairment in neuronal excitation-contraction coupling observed in these experiments is more pronounced in FF than FR and S units. We also anticipate that the observed impairments would be less in the soleus (SOL) muscle because, for the motor activities possible in a confined environment, SOL is presumably used to a greater extent than MG (3,6). Conversely, the observed deficits should be similar in another commonly studied muscle, extensor digitorum longus (EDL), because, like MG, its usage is limited during less demanding contractions (unpublished observations).

To address these issues, we intend to examine the dependence of the observed impairments on the fatigability of muscle by comparing the fatigue profiles of MG, SOL and EDL in exercise-deprived, exercised-exposed and wild rats. The existence of such a relationship would underscore the desirability of assuring an appropriate level of functional integrity of test muscles prior to the application of a disuse protocol to simulate weightlessness.
Fig. 1. Reduction in EMG and force output of the whole MG muscle of a cage-reared rat. Upper force profiles: averages of 8 supramaximal twitches (1 Hz). Lower force and EMG traces: single-sweep records of superimposed tetani (40 Hz). Stimulus duration: 2 ms for direct intramuscular stimulation (A, A1), 0.1 ms for muscle nerve (B, B1). Arrows (mins): stimulus sequence (interstimulus intervals). Fatigue test: 330 ms-duration 40 Hz stimulus trains at 1 Hz for two min. Records indicate 1st (B), 31st, 61st and 121st (B1) trains. Amplitudes of EMG (mean) and force (peak) expressed as reduction from "control" values (OZ). Insert: sites at which fatigue might occur during muscle-nerve stimulation (7).

REFERENCES
NEURAL FACTORS IN WHOLE-MUSCLE FATIGUE OF RAT SOLEUS AND MEDIAL GASTRONEMIUS MUSCLES. MJ Joyner,* RM Enoka,* LL Rankin,* KA Volz,* and DG Stuart* (intr. by D Van Wyck), Departments of Physiology and Physical Education, University of Arizona, Tucson, Arizona.

Inasmuch as fatigue can be defined as "... a failure to maintain the required or expected force" (Edwards, 1982), there are several sites between the command (supraspinal) and effector (muscle) centers at which this failure can occur. Among these are axonal-branch-point and neuromuscular-junction transmission failure. These aspects of fatigue were examined by comparing the force elicited in the soleus (n = 5) and medial gastrocnemius (n = 3) muscles of Sprague-Dawley rats (3.1-4.8 N) by nerve and direct-muscle stimulation before and after a fatigue test (6 min of 1 Hz trains with each train lasting 330 ms and including 13 stimuli; Burke et al., 1971). There was no difference in the mean peak twitch force obtained by nerve and direct-muscle stimulation before the fatigue test; the nerve-elicited values were 97.9 ± 5.9% of those obtained by direct-muscle stimulation. In contrast, this ratio was 77.9 ± 19.9% after the fatigue test. This post-fatigue test difference in the peak twitch force produced by nerve and direct-muscle stimulation before the fatigue test; the nerve-elicited values were 97.9 ± 5.9% of those obtained by direct-muscle stimulation. In contrast, this ratio was 77.9 ± 19.9% after the fatigue test. This post-fatigue test difference in the peak twitch force produced by nerve and direct-muscle stimulation before the fatigue test; the nerve-elicited values were 97.9 ± 5.9% of those obtained by direct-muscle stimulation. In contrast, this ratio was 77.9 ± 19.9% after the fatigue test. This post-fatigue test difference in the peak twitch force produced by nerve and direct-muscle stimulation before the fatigue test; the nerve-elicited values were 97.9 ± 5.9% of those obtained by direct-muscle stimulation. In contrast, this ratio was 77.9 ± 19.9% after the fatigue test. This post-fatigue test difference in the peak twitch force produced by nerve and direct-muscle stimulation before the fatigue test; the nerve-elicited values were 97.9 ± 5.9% of those obtained by direct-muscle stimulation. A quantitative approach is being used to assess the relationship between neurochemical muscle physiology and biochemical properties in isolated single fast-twitch motor units. Following collection of physiological data on single motor units the tibialis anterior muscle, transverse sections of muscle were stained for periodic acid Schiff and myofibrillar ATPase; alternate serial sections were immunohistologically stained. Fibers of the muscle unit identified histologically were dissected from the immunostained sections and analyzed biochemically with micromethodical techniques. Biochemical and physiological data were thus obtained on the same 4 fast-contracting-fatiguing motor units.

Values are means of 8 fibers (mole/kg dry wt/hr) with ± standard error of the mean.

This project addressed the effects of usage on muscle properties with the assumption that muscle-activity level is greatly influenced by the extent of the physical environment. When SD rats were given either a small (15-cage) or a large (476x cage) laboratory cage, the effects on fast-twitch (FT) mammalian muscle was controversial, perhaps because of the various "disuse" modes that reduce activity to different degrees. This paper introduces factors of muscle-activity level that can be studied independently. The major effects of this study arise from analysis of muscle-activity levels. The effects of usage on muscle-activity level are summarized below.

Low coefficients of variation in enzyme activities indicate a high level of biochemical uniformity (Nemeth, Petiot, Vrbau, J. Physiol. 1981) now on enzymes representing different biochemical pathways.

The results indicate that cage size had an effect on both SOL and EDL. The effects on force resistance and relaxation time were comparable for both EDL and SOL. However, fatigue resistance was clearly different. The large-cage rats developed a greater maximum fatigue index in SOL and a lesser normalized muscle weight for EDL. Supported by grants from NASA (NAG-338) and NIH (HL0729).

As an assessment of cage-size effects on the electromyogram (EMG), we have monitored the compound muscle action potential (AP) during a fatigue test in which the muscle was activated by supramaximal intermittent stimulation of its nerve. The effects on muscle force, the effects on fatigue in both SOL and EDL, and on the effects of usage and cage size in FT mammalian muscle were summarized. Joint fixation produced a decrease in muscle weight and absolute tension. The degree of atrophy was more severe with TTX-disuse and was accompanied by a decrease in tension. Fatigue was also increased with the TTX condition. The data suggest that the effect of cage size on muscle weight and absolute tension in both SOL and EDL was greatest with TTX-disuse. Supported by grants from NASA (NAG-338) and NIH (HL0729).

In an attempt to identify the mechanisms associated with the decline in force during a standardized fatigue test (Burke et al., J. Physiol. 234: 62, 1973), we have monitored, in vivo, the compound muscle action potential (AP) and the isometric force during a 6-min test in which the test muscle was activated by supramaximal intermittent stimulation of its motor nerve. Accordingly, we stimulated the soleus (SOL) and the extensor digitorum longus (EDL) muscles of male and female SD rats (1.36 and 2.65 N, respectively; 120-150 days) to subjects in a protocol that included 1 Hz trains of 13 stimuli delivered at a rate of 40 Hz. The APs were recorded with a pair of intramuscular stainless-steel electrodes and were quantified by average measurements of the area and "mean" amplitude (MA) for the 13 APs within each train (Stuart et al., Proc. XXIV IUPS XVI, 1983). The fatigability of the muscles was quantified by a measure of fatigue resistance (FR): peak tetanic force at 6 min relative to initial force. By raising the rats in small and large cages, the FR of both test muscles extended over a range of values such that the muscles clustered for each sex. The relationship between AP amplitude and MA was a curved one, the area of the fatigue test. In all 3 groups, the relationship was characterized by an initial potentiation and a subsequent parallel decline in both AP area and force. Quantification of fatigue resistance (FR) for SOL, these values (X ± SD) were 2.7 ± 0.6 (n = 10), 3.4 ± 0.6 (n = 7), and 3.6 ± 0.5 (n = 5), respectively, while for EDL, the values were 4.8 ± 2.5 (n = 10), 3.2 ± 0.5 (n = 7), and 2.7 ± 0.6 (n = 5), respectively. Despite these differences in FR for EDL, the 3 groups exhibited a qualitatively similar relationship between AP area and force during the course of the fatigue test. In all 3 groups, the relationship was characterized by an initial potentiation and a subsequent parallel decline in both AP area and force. Somewhat similar relationships were apparent between MA and peak force for EDL, although MA did not potentiate initially at any of the sites tested. The changes in AP area and MA during the test were similar for EDL (r2 = 0.83, p < 0.01). In contrast, the high and intermediate FR with potentiation for both EDL and SOL was significantly different from the low FR group in that essentially remained constant while AP area potentiated for the former groups and, conversely, area remained constant while force declined for the low FR group. In addition, the changes in AP area and MA for SOL, while significant (r2 = 0.01), were less related (r2 = 0.35) than for EDL.

The AP was apparent that under these conditions (also Sanderson et al., J. Appl. Physiol. 58: 1073, 1985) both AP area and MA changed during the course of the fatigue test. However, we are uncertain at this point as to whether these AP changes reflect a change in nerve impulse, a tissue-filtering effect, or some combination of the two mechanisms.

Supported by grants from NASA (NAGW 338) and NIH (HL0729).

The degree of potentiation of isometric twitch tension is dependent upon activation history and muscle-fiber type (Burke et al., Brain Res. 109: 353, 1976). In the present study, maximum voluntary muscle twitches before (pre) and after (post) a 6-min fatigue test, we observed greater stabilization in post-twitches than in pre-twitches in some muscles despite significant fatigue during the intervening test. These observations were based upon data acquired during a previously reported study on the effects of voluntary muscle potentiation on muscle properties in soleus (SOL) and extensor digitorum longus (EDL) muscles (Rankin et al., Soc. Neurosci. Abstr. 10: 781, 1980). The protocol included: (1) 32 twitches at 0.3 Hz (T1), (2) 1 Hz tetanus (T10) at 50-s (T10) tetanic fatigue test (T10) at 50 Hz repeated 15%; (3) 5 twitches at 0.3 Hz, and (4) 2 100-Hz tetan. Fatigue resistance was determined by expressing peak tetanic force at 6 min relative to the initial peak force. Mean values (± SD) for peak tension (P0), time-to-peak tension (TPT) and one-half relaxation time (fT) were determined for the 3 twitches immediately preceding (pre) and the 3 twitches following (post) the fatigue test. Twitch potentiation (P0/post P0 ± 1.0) was observed in 61% of EDL muscles despite mean 32% decline in peak force during the fatigue test. In contrast, only 33% of SOL muscles potentiated while force declined by 17% during the test. Given their fiber-type compositions (EDL = 3% SO, 97% FG, 3% FI; SOL = 80% SO, 16% FG), it was not surprising to find positive linear correlations between fatigue resistance and twitch potentiation in SOL (r2 = 0.79, p < 0.01). The correlation between TPT and NRT times were significantly larger in post-twitches (123% and 170%, respectively) for EDL, providing further evidence of musculature fatigue (Edward et al., J. Physiol. 1972). No significant changes in these values occurred in SOL. The change in TPT for EDL in association with potentiation is consistent with the notion that repetitive stimulation can alter the state of activation and hence the contractile state of the muscle (Wilkins, Br. Med. Bull. 17177, 1956).

The simultaneous occurrence of whole-muscle fatigue and potentiation suggests that the mechanisms underlying these two phenomena affect different sites within the muscle, but the linear relationship suggests that they are not totally independent of one another.

Supported by grants from NASA (NAGW 338) and NIH (HL0729).

ENDURANCE TIME CHARACTERISTICS OF THE DORSIFLEXORS AND PLANTARFLEXORS MUSCLES OF THE HUMAN ANKLE. A. Takahashi, R.A. Iversen, A. Layzer*, and I.V. Hunter (SPOH: R. Gallina), Biomedical Engineering Unit, Faculty of Medicine, McGill University, Montreal, Quebec, Canada, B2S 2R6.

Neuromuscular fatigue may be defined as any reduction in the force generating capacity of the muscle due to an increase in fatigue. Fatigue is independent of muscle pH and inorganic phosphates. Fatigue resistance was determined by expressing peak tetanic force at 6 min relative to the initial peak force. Mean values (± SD) for peak tension (P0), time-to-peak tension (TPT) and one-half relaxation time (fT) were determined for the 3 twitches immediately preceding (pre) and the 3 twitches following (post) the fatigue test. Twitch potentiation (P0/post P0 ± 1.0) was observed in 61% of EDL muscles despite mean 32% decline in peak force during the fatigue test. In contrast, only 33% of SOL muscles potentiated while force declined by 17% during the test. Given their fiber-type compositions (EDL = 3% SO, 97% FG, 3% FI; SOL = 80% SO, 16% FG), it was not surprising to find positive linear correlations between fatigue resistance and twitch potentiation in SOL (r2 = 0.79, p < 0.01). The correlation between TPT and NRT times were significantly larger in post-twitches (123% and 170%, respectively) for EDL, providing further evidence of musculature fatigue (Edward et al., J. Physiol. 1972). No significant changes in these values occurred in SOL. The change in TPT for EDL in association with potentiation is consistent with the notion that repetitive stimulation can alter the state of activation and hence the contractile state of the muscle (Wilkins, Br. Med. Bull. 17177, 1956).

The simultaneous occurrence of whole-muscle fatigue and potentiation suggests that the mechanisms underlying these two phenomena affect different sites within the muscle, but the linear relationship suggests that they are not totally independent of one another.

In the present study, we have determined the topography of somatostatin (SS), neuropeptide Y (NPY) and NADPH diaphorase (NADPH-d) neurons in human caudate and their relationships to zones of differential acetyl cholinesterase (AChE) activity (striosomes). Twelve blocks of striatal tissue fixed in neutral buffered formalin at 4°C for 48 hours. Sections were incubated for 24 h at room temperature with antisera to SS and YNP followed by amplification and detection using an avidin-biotin peroxidase method or indirect immunofluorescence. Absorption controls were consistently negative. NADPH-d staining was performed at room temperature with Triton X-100 (0.8%) and monosodium malate (125mg/ml). Sections were incubated in the incubation medium. These modifications enhanced staining, showed that nNOS and NADPH diaphorase immunocytochemistry and double simultaneous staining pattern of neuropil staining. Large numbers of reactive neurons were uniformly distributed throughout the caudate in bands and clumps which avoided zones of low AChE activity. This was especially striking in AChE, diaphorase double stained sections where neurons often congregated along the margins of high and low AChE activity. The background pattern of neuropil diaphorase activity was identical to that of nNOS. A neuronal mosaic was modified in the nucleus accumbens where the overall pattern appeared to be the superposition of two interdigitating patterns. Colocalization studies, including double diaphorase immunocytochemistry and double simultaneous immunofluorescence, showed that SS, YNP, and diaphorase activities coexist in a single population of neurons in human striatum. The morphological diversity of these neurons is variable and can be divided into 4 categories all of which are typical of aspiny type interneurons. Immunoreactive fibers were more prevalent in ventral caudate and accumbens suggesting that extrinsic projections, possibly from the basal forebrain, may contribute to higher levels of SS and YNP in these regions. (HMK is an MRC fellow, supported in part by NS 16367).

63.24 QUANTITATIVE AUTORADIOGRAPHY OF 7H-SPIRIPÉXIDE BINDING SITES IN RAT STRIATUM FOLLOWING DISCRETE CORTICAL LESION. J.M. Sol, 19* and C.F. Muench. Dept. of Neurology, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Using quantitative in-vitro film autoradiography we have studied 'H-epibatidine (1-3S) binding in normal striatum following a discrete cortical lesion. A single 1 cm2 cortical lesion was made on the frontal cortex. Sections were incubated for 60 min at room temperature for 30 min with 1 nM 1-3S in 50 mM tris-acetate-saline buffer, pH 7.4. Adjacent sections for non-specific binding were incubated in the presence of 100 fold excess of unlabeled epibatidine. Alternate sections were incubated for 90 min at room temperature in phosphate-buffered saline with 1 nM 1-3S, with and without 1 uM epibatidine. Autoradiographs were analyzed densitometrically with a Leitz HPR variable aperture microdensitometer

BASAL GANGLIA: IMMUNOCYTOCHEMISTRY

64.1 VARIABILITY OF AXODAL CONDUCTION VELOCITY MEASUREMENTS IN MAMMALIAN MOTOR UNITS. R.A. Gordon, T.N. Hand, P.M. Rankine, R.M. Enoka, and D.C. Stuart. Dept's of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ 85724.

The conduction velocity (CV) measurement is an important parameter in the study of neuromuscular transmission. The purpose of this investigation was to evaluate methods of determining CV of motor axons and to establish the reliability of the measurement.

Single motor axons to the functionally isolated tibialis posterior (TP) hindlimb were activated by suprathreshold stimulation of cut ventral-root (VR) filaments. Action potentials evoked in the TP muscle-nerve were recorded stereologically with three bipolar electrodes at the popliteal fossa level. CV measurements were made from VR to muscle-nerve (conventional CV) and between proximal and distal pairs of muscle-nerve electrodes (muscle-nerve CV).

The comparison of CV measurements revealed that the muscle-nerve CV was 5.2% slower, on average, excluding corrections for axonal conduction time, than the conventional CV estimate. Considerable variability, from a variety of potential sources, was observed in these values. Contributions to variability in CV could be attributed to variability in time and distance measurements as well as differences in stimulus utilization time, variable axonal branching, and variability in regional CV.

The variabilities inherent in distance and time measurements were estimated by making multiple measurements of these parameters. The CV error associated with each measurement was accounted for by the mean value of the distribution of CV estimates. This distribution was determined for each individual axon by calculating the logarithmic mean of the CV distribution and by calculating the variance among the CV estimates for all axons in the population. This method results in a standard error of measurement of CV estimates that was not accounted for by these error estimates.

The variability differences in the conventional and muscle-nerve CV estimates due to errors in time and distance measurements were calculated to be 0.9% and 9.8%, respectively. Comparison of the CV estimates and the degree of reliability is provided by the conventional measurement of CV in single motor axons, due to the longer conduction time compared to the short latency of the TP muscle-nerve CV. This is in contrast to sensory axons whose conduction time differs from motor axons, and in which other methods of measurement have been employed (Freedman et al., Experimental Neurology, 86(2): 208-226, 1985)

(SPO1: J.S. Angervnie). Dept's of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ 85724.

Previous studies from this laboratory (Enoka et al., and Rankin et al., Soc. Neurosci. Abstr. 10 (1984)) have indicated that the soleus (SOL) and extensor digitorum longus (EDL) muscles of rats were affected by the size of the cage in which the animals were raised. To continue our investigation of cage-size effects, we have examined some histochemical and fatigue-related characteristics in female hindlimb muscles.

Female SD weanling rats were raised for 100-135 days in either a small (SA) or large (LA) cage. The former is 125 times larger than the latter (LC/3/cage). Subsequently, fatigue-related characteristics were determined in vivo for the muscles SOL and EDL drawn from female rats that were significantly affected by cage size. In addition, cage size did not significantly affect the histochemical composition of either SOL, a fast-contracting muscle, or EDL, a slow-contracting muscle. These results do not support the existence of D-2 receptors on cortico-striatal terminals.

CAGE-SIZE AND GENDER EFFECTS ON FATIGUE IN RATS

Roger M. Enoka, Lucinda L. Rankin, and Douglas C. Stuart

Departments of Physiology and Exercise & Sport Sciences
University of Arizona
Tucson, AZ 85721

As a biological tissue, muscle adapts to the demands of usage. One traditional way of assessing contractile, nonweight-bearing, dorsiflexor muscle about 84% type SO and 16% type FOG muscle fibers digitorum longus (EDL). Soleus is a slow-contracting, cage females, large-cage females. Approximately 133x more surface area (floor + 4 walls). There were 6-7 rats in each of the 4 groups; Sprague-Dawley rats were raised in separate groups separated by gender, in each of the two large cages contained 3-4 rats while there were 6-7 animals, during rearing and of gender on the physiological properties of adult rat muscle.

METHODS

Adult (100-135 days old) male and female Sprague-Dawley rats were raised in separate groups from weaning age (21 days) in either of two cage sizes. The small cages (47 x 23 x 20 cm) each contained 3-5 rats while there were 6-7 animals, separated by gender, in each of the two large cages (320 x 183 x 99 cm). The large cages provided approximately 133x more surface area (floor + 4 walls). There were 6-7 rats in each of the 4 groups; namely, small-cage males, large-cage males, small-cage females, large-cage females.

The two test muscles were soleus and extensor digitorum longus (EDL). Soleus is a slow-contracting, antigravity, plantarflexor muscle which comprises about 84% type SO and 16% type FOG muscle fibers (1). In vivo electromyographic (EMG) recordings reveal constant motor-unit recruitment while the animal is awake (6). In contrast, EDL is a fast-contracting, owight-bearing, dorsiflexor muscle with a fiber-type distribution of about 8% SO, 57% FOG, and 37% FG (1). EMG recordings show that EDL is silent when the animal is at rest and activated phasically during locomotion (6).

In terminal experiments, with the rats under deep barbiturate anesthesia, the soleus and EDL muscles were surgically isolated and maintained in a paraffin-filled muscle bath at a temperature of 36°C. The following experimental protocol was used: 32 twitches were elicited by stimulation through the nerve to evaluate tetrap; 1 single tetanus at 100 Hz for 500 ms to determine the peak force; a standardized fatigue test (2) which involved intermittent stimulation (40 Hz) of the nerve; with trains of 13 stimuli, each train lasting 330 ms and occurring once each second; 8 twitches to evaluate post-tetanic potentiation; and finally, two 100 Hz tetani. Force was measured using a force transducer to which the tendon of the test muscle was attached via a low-compliance dacron line. The compound muscle action potentials generated by the stimuli were recorded with a pair of intramuscular stainless-steel wire electrodes. The 13 action potentials associated with each train of stimuli during the fatigue test were averaged; quantification was based on the average waveform. Measurements on the average waveform were made of area relative to the isoelectric line and of peak-to-peak amplitude. Statistical differences were assessed with a t-test for two means.

RESULTS

It is well documented that male rats are larger than the females of a similar age (7). This is apparent in Table 1 in the measurements of whole-body and test-muscle mass in that the female values averaged 67% of those for the males. These size differences, however, were not affected by cage size since within each of the 4 animal groups the mass of the two test muscles was not different; the average values for soleus and EDL were 0.23 and 0.25 g for the males and 0.17 g for both muscles in the females.

Qualitatively similar trends were apparent in the absolute force data in that there was no cage-size effect, but there was a partial gender effect. That is, the peak force exerted by EDL in response to a 330-ms train of 40 Hz stimuli was greater in males (X = 2.13 N) than females (X = 1.29 N). When the EDL force measurements were normalized relative to test-muscle mass, however, this difference disappeared. In contrast, the absolute 40 Hz force exerted by soleus was not affected by cage size or gender despite gender differences in soleus mass. However, normalization of soleus force did reveal a cage-size effect in that the force exerted per unit muscle mass of the small-cage males (6.0 N/g) was significantly less than the value for the large-cage males (7.9 N/g).

In addition to these measures of size and force, the ability of the test muscles to sustain activity was also examined. The 4 measurements used to characterize this capability were fatigue index (FI), relaxation time, area and· amplitude of EMG. These 4 parameters are used as indices of contractile fatigue (FI), 2, the "energy-state" of the muscle (relaxation time; 4), and precontractile fatigue (EMG; 3). The test muscles were subjected to a standardized fatigue test, and the 4 measures were made at selected intervals throughout the test; the final values are reported in Table 1. There were no cage-size effects among any of these parameters for the test muscles of the female rats. In contrast, the males exhibited 3 differences: 1) a cage-size effect for the FI of soleus; 2) a gender effect for the FI of the large-cage rats; 3) a combined (cage-size and gender) effect for the EMG area of small-cage EDL. Taken together, these results suggest that male rats are more sedentary in the small cages (decreased normalized muscle force and FI for
Table 1. An overview of the effects of cage size during rearing and of gender on size, contractile, and electromyographic (EMG) characteristics of the test muscles.

a Peak force at 40 Hz; b Ratio of the peak 40 Hz force at 6 min relative to the initial value. The protocol involved a standard fatigue test (Burke et al., 1973); c Difference in the time for the force to decline to 20% of the peak force at the end of the fatigue test (6 min) relative to the initial tetanus; d Values expressed relative to measurements on the initial average action potential; e Values are X (±SD); f p < 0.05 between males and females; g p < 0.05 between large and small cage

soleus) and more active in the large cages (increased soleus FI).

CONCLUSIONS
1. Cage size and gender had minimal effects on changes in the EMG measures.
2. Gender affected whole body mass, test muscle mass, and absolute force.
3. Cage size and gender affected normalized force and fatigability.
4. Since the cage-size effects were only present in the male rats, these results suggest caution in the interpretation of results based on this animal model.
