IMPROVED SOLUTION OF THE LIDAR EQUATION
UTILIZING PARTICLE COUNTER MEASUREMENTS

The extraction of particle backscattering from incoherent
lidar measurements poses some problems. In the case of
measurements of the stratospheric aerosol layer the solution of
the lidar equation is based on two assumptions which are
necessary to normalize the measured signal and to correct it
with the two-way transmission of the laser pulse.
Normalization and transmission are tackled by adding the
information contained in aerosol particle counter measurements
of the University of Wyoming to the ruby lidar measurements at
Garmisch-Partenkirchen.

The widely accepted lidar normalization is the matching
method which assumes a range existing in the stratosphere with
negligible particle backscattering. The signals from such a
range, usually from above 25 km, are adjusted to match the
expected molecular return which is calculated from radiosonde
density (or standard atmosphere) data.

The two-way transmission becomes an important correction
when rather dense volcanic eruption clouds are observed. The
correction is calculated from the extinction the laser pulse
experiences on its way to and from the scattering volume under
observation. The extinction in turn is calculated from
particle backscattering measured by lidar thus causing an
iterative calculation loop. The conversion factor involved,
the backscatter-to-extinction ratio, is the crucial point in
this procedure. For background or aged volcanic aerosol a
value of about 0.015 1/sr is accepted (e.g. Russell and Hake,
1977), whereas much higher values are expected from fresh
volcanic aerosols. Some values have been reported for the El
Chichon period which are as high as 0.029 1/sr (Swissler et
al., 1984).

Both quantities, normalization and transmission
correction, can be calculated if the particle size
distribution and the index of refraction are known. The
balloon-borne particle counter soundings of the stratosphere by
the University of Wyoming provide such data which allow the
calculation of

i time resolved particle backscattering from the
height level of matching (which then adds to
the molecular backscattering at this level)

ii time and height resolved backscatter-to-
exctinction ratios
The cumulative particle concentrations of the six counter channels are differentiated with a height resolution of 1 km to fit a bimodal lognormal distribution. This model allows the description of the aerosol by 6 parameters (two modal radii, two modal widths and the total number concentrations in each distribution), thus providing for the proper treatment of the increased number of large particles after volcanic eruptions (Hofmann et al., 1983).

Calculated backscattering from height levels above 25 km for the E1 Chichon period will be compared with lidar measurements and necessary corrections will be discussed. The calculated backscatter-to-extinction ratios will be compared to those, which have been derived from a comparison of published extinction values (Rosen and Hofmann, 1986) to measured lidar backscattering at Garmisch (Jäger et al., 1984). These ratios have been used to calculate the Garmisch lidar returns. For the period 4 to 12 months after the E1 Chichon eruption a backscatter-to-extinction ratio of 0.026 1/sr has been applied with smaller values before and after that time.
