Report prepared by Janet Franklin
ABSTRACT

We are using geometric/optical canopy reflectance modeling and spatial/spectral pattern recognition to study the form and structure of savanna in West Africa. We are testing an invertible plant canopy reflectance model for its ability to estimate the amount of woody vegetation cover in areas of sparsely wooded grassland from remotely sensed data.

Dry woodlands and wooded grasslands, commonly referred to as savannas, are important ecologically and economically in Africa, and cover approximately forty percent of the continent by some estimates. The Sahelian and Sudanian savanna make up the important and sensitive transition zone between the tropical forests and the arid Saharan region. The depletion of woody cover, which is used for fodder and fuel in these regions, has become a very severe problem for the people living there. We are using Landsat Thematic Mapper (TM) data to stratify woodland and wooded grassland into areas of relatively homogeneous canopy cover, and then applying an invertible forest canopy reflectance model to estimate directly the height and spacing of the trees in the stands. Since height and spacing are proportional to biomass in some cases, a successful application of the segmentation/modeling techniques will allow direct estimation of woody biomass, as well as cover density, over significant areas of these valuable and sensitive ecosystems.

Sahelian savanna sites in the Gourma area of Mali being used by the NASA/GIMMS project (Global Inventory Modeling and Monitoring System, at Goddard Space Flight Center), in conjunction with CIPEA/Mali (Centre International pour l'Elevage en Afrique) will be used for testing the canopy model. The model will also be tested in a Sudanian zone crop/woodland area in the Region of Ségou, Mali.

1. INTRODUCTION

About noon we saw at a distance the capital of Kaarta, situated in the middle of an open plain — the country for two miles around being cleared of wood by the great consumption of that article for building and fuel...[February 11, 1796] (Park 1893)

The need for accurate baseline data on the type and condition of landcover for large areas of the earth has been recognized by many leading scientists (NASA 1983, Houghton et al. 1983, Woodwell 1984). Terrestrial biota greatly affect the climate, energy budget, hydrologic cycle and biogeochemistry of the Earth, and are in turn affected by these processes. Quantifying the effects of human impact on the biosphere requires a greatly improved understanding of the influence of human-induced changes in land cover (such as deforestation, "desertification," and conversion of land to agricultural and urban uses) on the spatial and temporal dynamics of terrestrial vegetation. This understanding may in turn help resource planners improve land use practices in areas where degradation of range and farmland and loss of fuelwood contributes to problems of starvation and disease.

Global land-cover information is traditionally derived from small-scale vegetation maps and FAO statistics, and more recently from satellite imagery (Tucker et al. 1985, Justice et al. 1985, Matthews 1983). These estimates vary considerably, due to lack of consistency between data sources, particularly concerning classification and methodology (Ajtay et al. 1979, Matthews 1983). The accurate assessment of land cover and biophysical parameters of woody vegetation, such as productivity, biomass, albedo, canopy height (surface roughness), surface temperature, and evapotranspiration, are important for determining the relationship between the land surface and the atmosphere and for driving models of climate, energy balance and biogeochemical cycling (Botkin et al. 1984, Hobbie et al. 1984).
Degradation of arid and semi-arid ecosystems has accelerated in recent years due to increased human use for fuel and food production, coupled with climatic fluctuation. Degradation is defined as a reduction in perennial phytomass and ecosystem productivity, elimination of woody cover, soil exposure, compaction, and erosion, and loss of stored nutrients and carbon (Dregne 1983, Petrov 1976, Vinogradov 1980, Reining 1978, and Hare 1983). This has occurred in sub-Saharan Africa, particularly the Sahel, in the last two decades. Mungo Park’s remarks about the kingdom of Ségu (now Mali) in the quote that opens this section show that this is not a new problem (Park 1893), but now, for the first time in history, drought and famine are international media events.

Several feedback mechanisms for prolonging droughts and accelerating land degradation have been proposed which involve land cover change. Because rain is primarily of convective origin in the tropics and subtropics, the source of the water either being the ground itself or a neighboring ocean, once a drought begins, the vegetation dies, reducing evapotranspiration and convective rainfall even further. Another feedback model states that the loss of vegetation causes increased surface albedo, drastically changing the energy balance of the surface, resulting in further drying (Charney 1975). However, in many parts of the Sahel zone the surface albedo again decreased after the drought period in the early 1970’s (Rasool et al. 1982), implying that a runaway process of perpetuating the drought through increased surface albedo did not occur. Changes in evapotranspiration may be a more significant factor in perpetuating droughts (Rasool 1983). Therefore, changes in the amount of woody vegetation should be examined.

In the development of remote sensing techniques for vegetation assessment, the spectral vegetation indices and transforms that have been applied successfully to estimate vegetation amount in agricultural and grassland ecosystems do not work as well in forests and semi-arid woodlands, bush, and shrublands, because the bulk of the biomass is not green biomass but in the woody structures. Absorption and shadowing by woody parts and the amount of bare soil visible has a complicated effect on greenness measures. Thus, it is important to account for the ecosystem architecture. Further, the information classes in remotely sensed scenes of arborescent
landscapes are composed of spectral mixtures of objects (such as trees, shrubs, grass, and soil) and form a mosaic at the scale of satellite sensor resolution.

We are testing a geometric/optical canopy reflectance model which exploits the canopy geometry in an inversion technique to predict tree height and density. This model is applied in a savanna ecosystem, an ecosystem of great importance in terms of global ecology and human utilization. Our approach is:

— spatial pattern analysis of imagery,
— image stratification into woodland stands of homogeneous density, and
— application of the canopy model within woodland stands.
2. BACKGROUND

The main methods used for measuring vegetation amount, form, and structure from remotely sensed data are (1) spectral pattern recognition, including clustering, classification and labeling (Franklin et al. 1986), and (2) establishing correlative relationships between vegetation characteristics and satellite reflectance data. In spectral pattern recognition and image classification (Haralick and Fu 1983), cover classes are identified, and vegetation characteristics are associated with the classes through stratified sampling and measurement. Inference of vegetation parameters (biomass, chlorophyll absorption, moisture content, color and spectral signature) from remotely sensed data is discussed by Jensen (1983) and Curran (1980). In brief, the estimation of such parameters by correlation with band ratios and/or linear transforms usually relies on the contrast between the visible absorption and infrared reflectance of green vegetation. Woody vegetation amount (tree or shrub cover), where vegetation cover is incomplete (particularly in semi-arid and arid environments) is more strongly related to spectral brightness than any other spectral transform (Colwell 1981, Olsson 1984 and 1985, Logan and Strahler 1982, Pech et al. 1986). This effect has been modeled by Otterman (1984 and 1985).

Another method of inference in remote sensing is proportion estimation, treating the reflectance of a pixel as a linear composite of the reflectance of scene components weighted by their relative area within the pixel. This method has been used to estimate vegetation amount in canopies with incomplete cover (Richardson et al. 1975, Jackson et al. 1979, Heimes and Smith 1977, Graetz and Gentle 1982, Pech et al. 1986).

2.1. Plant Canopy Reflectance Modeling

In contrast to pattern recognition, where scene elements are mapped into information classes based on their radiance measures, or spectral indices, where a biophysical parameter is related empirically to (transformed) spectral data, in reflectance modeling reflectance is predicted as a function of the physical and optical properties of the scene elements. Plant canopy reflectance modeling will be defined as one way of treating mathematically the interaction of electromagnetic
radiation with "scene elements", where the scene element is a leaf (sub-element) or canopy (aggregate). The approaches used are radiative transfer theory in the visible and near-infrared wavelengths and the energy balance equation in the thermal regime. The goal in plant canopy modeling is to predict the optical reflectance or emission as a function of intrinsic biophysical properties of the scene elements. If the canopy model can be inverted, then canopy characteristics can be inferred from measured reflectance. This is analogous to the technique used by atmospheric scientists who deduce profiles of properties (temperature, aerosols, etc.) from integrated radiance measures.

Strahler et al. (1986) and Smith (1983) review canopy modeling from a remote sensing viewpoint; the plant stand is being viewed by a sensor measuring electromagnetic radiation, and the signal received at the sensor is a function of the intrinsic properties of the target (the plant stand) and the other elements in the scene (such as atmosphere, soil, shadowing as a function of sun-sensor-surface geometry, and stand density and homogeneity). The problem in reflectance modeling is separating reflectance due to intrinsic properties of the plant stand from extrinsic properties due to varying irradiance, or atmosphere.

Ross (1981) also discusses the modeling of plant stands. His treatment is founded in a Russian tradition of agronomic research which applies phytometry (the large scale estimation of stand architecture) to model the radiation and water regime in a crop canopy. This is done to link the biophysical attributes of the plant stand to its productivity. This agronomic perspective has been paralleled in England and the U.S. by Montieth (1982) and Gates (1980). Ross (1981) states:

If statistical phytometry is to be developed further, one-dimensional plane-parallel models of canopy reflectance must be abandoned and the stand treated statistically as a population of individual plants.

Similarly, Smith (1983, p. 87) concludes:

Because of the large random component in radiation modeling, tractable models will include a statistical component. . . . When significant spatial variation occurs in the horizontal direction such that plane-parallel approximations to the scattering and emissive terrain elements are no longer valid . . . the three-dimensional structure of terrain elements becomes important and leads to the casting of distinct shadows resulting from the macrostructure and morphology of the elements. For vegetation targets a merging of radiative transfer theory and geometric optics is evident.
The model that we will apply treats the stand statistically as a population of individual plants, and uses geometric optics to predict the shadowing from the plant canopy.

2.2. Inversion of Canopy Models

Canopy models can use two sources of information for inversion; angular variation in response, and covariance statistics of estimated mixtures across pixels (Smith 1983). Goel et al. (1984), Goel and Thomas (1984a and b) and Goel and Strebel (1983) show how numerical non-linear optimization techniques can be used to invert the Suits (1972) or SAILS (Verhoef and Bunnick 1976) type model to obtain leaf area from directional reflectance measurements if the other parameters of the model are known (solar and viewing zenith, azimuth between solar and viewing direction, leaf inclination distribution, leaf hemispherical reflectance and transmittance, soil hemispherical reflectance, and fraction of incident diffused light). Goel and Deering (1985) do the same thing but predict five of the model parameters through inversion, holding only soil hemispherical reflectance and skylight constant. The success of inversion is limited by how well the model actually predicts reflectance for a given canopy (runs in the forward direction). In the papers cited above the inversion underestimates leaf area in the infrared wavelengths (the model overestimates reflectance) at low sun angle and for sparse canopies, because the model doesn’t account for shadowing.

Inversion of these models in a remote sensing situation may not be practical because one either has to measure complete hemispherical reflectance (not very practical even from a multi-look angle sensor because of the number of measurements needed), or estimate spectral parameters, which are dependent on cover type and soil background (even among agricultural types), and diffuse light, which depends on atmospheric conditions. This technique couldn’t be used unless the cover type and estimations of these parameters were already known, but could be useful in an agricultural monitoring scenario (Jackson 1984).

The plane-parallel models have been important in understanding radiative transfer in vegetation canopies, especially in describing the bidirectional reflectance distribution function (BRDF)
of the canopy given certain properties of leaf area, angle and azimuth distribution, leaf and soil BRDF, and so forth. However, these models do not account for variation in reflectance as a function of spatially heterogeneous vegetation cover. If prediction of scene properties is the goal, these models do not adequately bridge the gap to the pattern recognition (indirect inference) techniques. The models which employ geometric optics better describe actual canopies, both agricultural and natural, because they incorporate canopy geometry and treat biological populations statistically.

The geometric-optical models use the second information source, covariance statistics of estimated mixtures across pixels, for inversion. This is more practical in a satellite remote sensing situation, but still there are several scene and canopy parameters that must be measured or estimated.

2.3. Li-Strahler Canopy Models

Li and Strahler (1985) (see also Li 1981, Li 1983) developed a series of invertible, deterministic canopy reflectance models for sparse pine forest (i.e., forest with a discontinuous canopy). These models are invertible because parameters of tree height and density can be directly calculated from remotely sensed reflectance values, given appropriate ground calibration. The models are essentially geometric in character, treating trees as solid objects on a contrasting background, and estimates the proportion of each pixel in green canopy, shadow, and understory. In the simple canopy model the following assumptions are made:

1. a pine crown is a simple cone with fixed base/height ratio;
2. the crown, although conical in shape, can be modeled as a flat Lambertian reflector which absorbs visible wavelengths differentially (i.e., is green);
3. tree heights are lognormally distributed with a fixed mean and variance and a known coefficient of variation;
4. tree counts from pixel to pixel vary as a Poisson distribution function with a fixed density of individuals per unit/area;
5. the ground surface underlying the forest canopy (e.g., understory) has a signature which is distinctly different from that of tree crowns and shadow; and
Assumption 4 was later modified because a Neyman type A (double Poisson) model was shown to fit better the distribution of tree counts in 80 m quadrats (corresponding to MSS pixels) interpreted from aerial photographs.

The simple model can be thought of as including two steps. First is "proportion estimation," or calculating the proportions of understory, illuminated crown area, and shadow in each pixel. Because these proportions are a direct function of the number and size of trees that appear in a pixel (providing that neither the crowns intersect nor shadows overlap), they can be used to calculate a dimensionless parameter, $NR^2$, for each pixel, where $R^2$ is the square of the average cone radius and $N$ is the density of cones per unit area. The second step requires calculating the mean and variance of $NR^2$ values for all pixels within a stand, and using these values to estimate the mean height and spacing parameters for lognormal and Poisson/Neyman Type A models. Because inversion of the model to obtain tree height and spacing requires calculation of interpixel variance, a homogeneous timber stand of certain minimal area (perhaps twenty pixels) is needed. This version of the Li-Strahler model is referred to as the "simple variance-dependent model."

Using this model, Li and Strahler estimated height and density parameters to within 10 percent of values obtained from air photos for pine stands in northern California, U.S.A. The accuracy of the simple variance-dependent model is limited by the overlapping of crowns and shadows, which becomes significant when canopy cover reaches a level of about 30 to 40 percent, depending on the shape of the trees and their angle of illumination. A modified overlapping model accounts for overlapping of shadows and intersection of crowns as density increases and trees are spaced increasingly close to each other, and can be inverted accurately for stands of up to 75% or greater crown closure, if the trees are not too small (Li and Strahler 1985).
2.3.1. Simple Variance-Dependent Model

To reiterate, in the simple variance-dependent model the reflectance of a pixel is modeled as a linear combination of scene components weighted by relative areas. Pixels from an area of homogeneous tree cover can be taken as replicate measurements of reflectance. Interpixel variance in reflectance comes from three sources:

- variations in the number of trees among pixels
- variation in tree size within and between pixels
- chance overlap of crown and shadow within a pixel.

The assumptions of the simple model, modified to fit the savanna tree form, are:

- tree shape can be approximated by a simple shape, a semisphere on a stick, or some other form (see Figure 1),
- tree shape is uniform (independent of size), and size and density are uncorrelated,
- size is described by a known distribution function, and even if the mean is not known, the coefficient of variation (CV, standard deviation divided by mean) is known,
- spatial pattern (distribution of the number of trees per pixel) can be described by a distribution function (e.g. Poisson, double Poisson) so that, again, even if the mean density is not known, the CV is (or the CD, coefficient of determination, variance divided by mean).

The sensor model associated with the simple canopy model is based on the following assumptions:

- the output of the sensor is a digital image, consisting of brightness values averaged over the spatial extent of each grid cell,
- the sensor is multi-spectral, and
- the sensor is sufficiently far from the ground that view angle can be considered vertical and uniform over the imaged area.

2.3.2. Geometry of the Model

Figure 1 shows the geometry of a semisphere on a stick illuminated at angle $\theta$. The radius of the semisphere is $r$, and $h$ is the height to the base of the crown. Let $r^2$ be the square of the crown radius. Let $\gamma = \tan^{-1}(h/r)$. The illuminated crown, shadowed crown and shadowed ground projected to the sensor will have areas:

Crown: \[ \frac{\pi}{2} r^2 (1 + \cos \theta) \]
Shadowed Crown: \[ \frac{\pi}{2} r^2 (1 - \cos\theta) \]

If \( h \tan\theta > 2r \)

Shadowed Background:

\[ \frac{\pi}{2} r^2 (1 + \frac{1}{\cos\theta}) \] (large sun angle or tall narrow trees)

or if \( h \tan\theta < 2r \)

Shadowed Background:

\[ \frac{\pi}{2} r^2 (1 + \frac{1}{\cos\theta}) - 2r^2 (t + \frac{1}{\sin 2t}) \] (small sun angle or short wide trees)

where \( t = \cos^{-1} \frac{h \tan\theta}{2r} = \frac{\cos^{-1} \tan\theta}{2\tan\gamma}. \)

In the original formulation, Li (1981) treated shadowed crown and background as one component, with a single signature, and the area calculated from tree geometry.

We will define \( \Gamma \) as the geometric factor, such that \( \sum_{i=1}^{n} r_i^2 \) is the area of the pixel covered by tree and shadow. Therefore,

\[ \Gamma = \pi + \frac{\pi}{2} (1 + \frac{1}{\cos\theta}) \quad \text{or} \quad \Gamma = \pi + \frac{\pi}{2} (1 + \frac{1}{\cos\theta}) - 2r^2 (t + \frac{1}{\sin 2t}) \]

2.3.3. Variables and Notation

1) **Variables Associated with Tree Crowns:**

- \( r \) Radius of crown as semisphere, lognormally distributed.
- \( h \) Height to base of crown, lognormally distributed. Crown height, \( H = r + h \).
- \( \alpha \) Equal to \( h/r \). Assumed constant within a stand.
- \( C_h \) Coefficient of variation (ratio of standard deviation to mean) for heights.
- \( C_r \) Coefficient of variation of radius. If \( \alpha \) is fixed, then \( C_h = C_r \) since \( r \) is a linear function of \( h \).

2) **Variables Associated with a Pixel:**
A Pixel size. Usually taken as having a unit area.
n Number of trees in a pixel, distributed as a Poisson; independent of other variables.

\( R^2 \) Average of squared crown radii within the pixel, i.e., \( R^2 = \frac{1}{n} \sum_{i=1}^{n} r_i^2 \).

\( m \) Dimensionless. Ratio of sum of squared crown radii to area of pixel, which is

\[ m = \frac{nR^2}{A} = \frac{1}{n} \sum_{i=1}^{n} r_i^2 / A. \]

Note that \( m \) is a dimensionless parameter reflecting both the size and density of trees.

The larger \( m \), the larger or denser the trees. This is scaled by the geometric factor, \( \Gamma \), to get the proportion of pixel in canopy, shadow and background.

3) Variables Associated with the Timber Stand:

\( N \) Mean of \( n \) for all pixels. For the fully random model, this is the value of the Poisson parameter.

\( C_d \) Dispersion coefficient (variance-to-mean ratio) of \( n \). That is, \( C_d = V(n)/N \). If \( n \) is distributed as a Poisson function, \( C_d \approx 1 \). If not, \( C_d \) will depend on the pixel size, \( A \).

For the clumped or patchy distributions that characterize large quadrats in natural forests, \( C_d \) will increase with \( A \).

\( H \) Population mean of \( h \).

\( E(r) \) Population mean of \( r \).

\( V(r) \) Population variance of \( r \). \( V(r) = C_r^2 (E^2(r))^2 \).

\( E(r^2) \) Population mean of \( r^2 \).

\( V(r^2) \) Population variance of \( r^2 \).

If \( r \) is lognormally distributed, then \( r^2 \) is also lognormally distributed. We can then show from the definitions of \( E \) and \( V \) that

\[ E(r^2) = (1 + C_r^2)E(r)^2, \]

and

\[ V(r^2) = \omega [E(r^2)]^2, \]

where

\[ \omega = (1 + C_r^2)^4 - 1. \]

\( R^2 \) Mean value of \( R^2 \) for all pixels. i.e., \( E(R^2) \).
The square root of $R^2$, i.e., $\sqrt{E(R^2)}$.

$V(R^2)$ Variance of $R^2$.

If $n$ is a constant and $r$ is randomly distributed in the spatial domain, then $R^2 \approx E(r^2)$. Also, $R^2$ is a sample mean, and thus $V(R^2) = V(r^2)/n$.

$M$ Mean of $m$ for all pixels in the stand.

$V(m)$ Variance of $m$.

### 2.3.4. Reflectance of an Individual Pixel

As stated above, we model the reflectance of the pixel as an area-weighted sum of the reflectances of the four spectral scene components.

1) **Areas and Proportions:** Next are variables describing areas or proportions for scene components.

- $A_g$ Area of illuminated background within the pixel.
- $A_c$ Area of illuminated crown within a pixel.
- $A_s$ Area of shadowed background within a pixel.
- $A_t$ Area of shadowed crown within a pixel.
- $K_g = A_g / A$ Proportion of pixel not covered by crown or shadow.
- $K_c = A_c / (A - A_g)$ Proportion of area covered by crown and shadow that is in illuminated crown.
- $K_t = A_t / (A - A_g)$ Proportion of covered area in shadowed crown.
- $K_s = A_s / (A - A_g)$ Proportion of covered area in shadowed background.

From the tree geometry described above, we can show that

$$A_c = m \frac{\pi}{2}(1 + \cos \theta)$$

$$A_t = m \frac{\pi}{2}(1 - \cos \theta)$$

$$A_s = m \frac{\pi}{2}(1 + \frac{1}{\cos \theta}) \text{ if } h \tan \theta < 2R$$

or

$$A_s = m \frac{\pi}{2}(1 + \frac{1}{\cos \theta}) - 2r^2(t - \frac{1}{\cos \theta} \sin 2t) \text{ if } h \tan \theta > 2R$$
So,

\[ A_e + A_t + A_s = m \Gamma \]

and

\[ A_\varphi = 1 - m \Gamma. \]

2) \textit{Reflectance Vectors}: These are average single channel reflectances or multispectral reflectance vectors.

G \hspace{1cm} \text{Reflectance vector for a unit area of illuminated background (constant).}
C \hspace{1cm} \text{Reflectance of a unit area of illuminated crown (constant).}
Z \hspace{1cm} \text{Reflectance of a unit area of shadowed background (constant).}
T \hspace{1cm} \text{Reflectance of a unit area of shadowed crown (constant).}
S \hspace{1cm} \text{Reflectance of a pixel. Variable; depends on number and size of trees in pixel.}

The signature of pixel \( i \) in band \( j \) (for single channel, drop the subscript \( j \)) is

\[ S_{ij} = (G_j \cdot A_g + C_j \cdot A_c + Z_j \cdot A_z + T_j \cdot A_t)/A \] (1)

3) \textit{Geometric Relationships}: From the geometry of the semisphere, we have the following relations if the pixel is taken to have a unit area:

\[ (A - A_e) = \sum_i r_i^2 \Gamma = Am \Gamma \]

\[ (A - A_\varphi) = A_e + A_t + A_s \]

\[ K_\varphi = 1 - m \Gamma \]

\[ K_e = (\frac{\pi}{2} (1 + \cos \theta))/\Gamma \]

\[ K_z = (\frac{\pi}{2} (1 + \frac{1}{\cos \theta}))/\Gamma \]

\[ K_t = (\frac{\pi}{2} (1 - \cos \theta))/\Gamma \]

\[ 1 = K_e + K_z + K_t. \]
Equation (1) can be formulated:

\[ S = K_g \cdot G + (1-K_g) \cdot (K_c \cdot C + K_z \cdot Z + K_t \cdot T) \]  \hspace{1cm} (2)

Since \( K_c, K_z, \) and \( K_t \) sum to one, the expression \( (K_c \cdot C + K_z \cdot Z + K_t \cdot T) \) represents a point in multispectral space lying within a triangle with vertices at \( C, Z, \) and \( T \) (see Figure 2). This point is \( X_0 \); the average reflectance of a tree and its associated shadow. The only variable in the right side of (2) is thus \( K_g \), which is a linear function of \( m \). When \( m \) varies, \( S \) will vary along a straight line connecting points \( G \) and \( X_0 \).

Note that as overlapping of trees and shadows occurs, the background is obscured and shadows falling on other crowns will be foreshortened. Therefore, the reflectance of a pixel that is all tree and shadow, \( X_{\infty} \), will lie on line \( TC \), its position depending on tree geometry and sun angle.

Substituting the geometric expressions above for \( K_c, K_z, \) and \( K_t \) into (2) yields

\[ S = G - Gm \Gamma + X_0 m \Gamma \]

Rearranging, we have

\[ m \Gamma (G-X_0) = (G-S) \]  \hspace{1cm} (3)

In the last expression, \( G-S \) and \( G-X_0 \) are vector differences; however, \( G-S \) lies on the line \( G-X_0 \) and therefore the equation is actually scalar. Using the notation \( |GS| \) to indicate the length of the vector connecting \( G \) and \( S \), we have

\[ m = \frac{|GS|}{\Gamma |GX_0|} \]  \hspace{1cm} (4)

If there were no error in the signal, the \( m \) value determined in any band would be the same, but noise will be present in \( S, \alpha, \) and the component signatures. Two averaging procedures can be used; the weighted average of \( m \) values for all bands, or the weighted average of the final estimates of height and spacing. In the single band case, the outliers will inflate the variance more, making the trees appear bigger.
The sensitivity of this model to noise in $S$ and the component signatures, and to errors in estimation of parameters can be shown by taking the partial derivative of $m$ with respect to these variables. Rearranging and expanding (3) we get

$$m = \frac{G}{\Gamma(G - X_0)} - \frac{S}{\Gamma(G - X_0)} = \frac{G}{\Gamma(G - X_0)} - \frac{1}{\Gamma(G - X_0)} \cdot S$$

(5)

and from this,

$$\frac{\partial m}{\partial S} = \frac{1}{\Gamma(G - X_0)}$$

(6)

$$\frac{\partial m}{\partial G} = \frac{S - X_0}{\Gamma(G - X_0)} \approx \frac{1}{\Gamma(G - X_0)}$$

(7)

(because when cover is low, $S \approx G$)

$$\frac{\partial m}{\partial X_0} = \frac{G - S}{\Gamma(G - X_0)^2} \approx \frac{m}{G - X_0}$$

(8)

$$\frac{\partial m}{\partial \Gamma} = \frac{S - G}{\Gamma^2(G - X_0)} \approx \frac{m}{\Gamma}$$

(9)

Because $(G - X_0)$ is in the denominator, when the spectral contract between background and tree is high, sensitivity to noise in $S$, $G$ and $X_0$ will be reduced. When density is low ($m$ is small), noise or error in estimating $X_0$ and $\Gamma$ are less important than the contrast between tree and background $(G - X_0)$, because $m$ is in the numerator.

2.3.5. Inverting the Model using the Variance of $m$

Assume that a timber stand consists of $K$ pixels, $i = 1, \ldots, K$. From (2), we can obtain a value of $m$ for each pixel. Then, the values of $m$ will have a mean and a variance within the timber stand:

$$M = \frac{1}{K} \sum_{i=1}^{K} n_i R_i^2 ;$$

$$V(m) = \frac{1}{K} \sum_{i=1}^{K} (n_i R_i^2 - M)^2 .$$
Let us now assume that height (and thus $r$) is independent of density. Thus, expressions for the mean and variance of independent products will apply:

$$M = E(nR^2) = E(n) \cdot E(r^2) = NR^2,$$

and

$$V(m) = V(nR^2) = (R^2)^2 V(n) + N^2 V(R^2) + V(n) V(R^2).$$

Because $n$ is a Poisson function,

$$V(n) = N.$$

Further,

$$V(R^2) = V(r^2)/n \approx V(r^2)/N = w(E(r^2)^2)/N.$$

Substituting (12) and (13) into (11), we finally obtain:

$$V(m) \approx (N + wN + w)(R^2)^2 = (M + wM + wR^2)R^2.$$

In order to derive (14), $R^2$ and $V(R^2)$, which are parametric terms, are approximated using the sample mean and variance of $r^2$. Small errors are introduced by these approximations, but they may be ignored for our purposes. Solving (14) for $R^2$, we obtain:

$$R^2 = \frac{[(1 + w)^2 M^2 + 4V(m)w] - (1 + w)M}{2w}.$$

Thus, given sample estimates of the mean and variance of $M$ determined from the reflectances of pixels in the stand, we can solve for $R^2$, and then for $N$, yielding the average size and density of trees in the stand. The assumption underlying the use of the sample variance of $r^2$ as $V(R^2)$ is that each pixel is an independent sample of values of $r^2$. Other approximations can be also applied to (11). For example, if the interpixel variation of $r^2$ is more significant than intrapixel variation, we may use $V(R^2)$ directly as an approximation of $V(r^2)$. Then (14)
becomes:

\[ V(m) = (1 + w)M R^2 + wM^2 \]

and we obtain:

\[ R^2 = \frac{V(m) - wM^2}{(1 + w)M} \]

Also, if the dispersion coefficient of \( n \) is significantly different from 1, we may use \( V(n) = NC_d \).

Then (15) becomes:

\[ R^2 = \frac{((C_d + w)^2M^2 + 4V(m)wC_d) - (C_d + w)M}{2wC_d} \]

The choices basically depend upon what \( \text{\textit{a priori}} \) information we have (Li and Strahler 1985).
3. STUDY AREA

3.1. The Savanna Biome

The study is being conducted in the Sahelian and Sudanian zone savannas of West Africa. Dry woodlands and wooded savanna (with tree cover greater than 10%) are presently estimated to cover 486.4 million ha or 22.2% of the continent of Africa, including 8.6 million ha in Mali (Lanley and Clement 1982). Savanna will be defined as the subtropical and tropical vegetation formations where the grass stratum is continuous and important, occasionally interrupted by trees and shrubs (cover greater than 10% and less than 80%), where fire occurs, and where the growth is closely associated with alternating wet and dry seasons. The savanna forms the broad transition between closed tropical forest and open desertic steppes (Bourlière and Hadley 1983).

Because of the difficulties in estimating changes in savanna and dry woodland area using available monitoring techniques, the most authoritative study declines to estimate changes in these categories (Lanley and Clement 1982). However, the rate of conversion to other vegetation types by clearing for agriculture, grazing, burning and fuelwood harvesting appears to be very high. For example, in Tanzania, miombo and other dry woodlands in populated areas are being harvested more rapidly than they can regenerate (Allen 1983). The problem in drier savanna in the Sahel may be even more severe (Delwaule 1973).

The balance between woody and herbaceous plants, and the effects of various factors on this balance is one of the most interesting aspects of the dynamics of savanna ecosystems (Bourlière and Hadley 1983, Lebrun 1955). Walker and Noy-Meir (1982) have proposed a model of savanna structure based on the idea of dynamic equilibrium, which assumes that the strata compete for topsoil water, and an increase in tree leaf biomass must be balanced by a decrease in herbaceous biomass (shown empirically in the Sahel by Breman 1982). Although the strata are in competition for soil moisture, the woody strata also create favorable microhabitat for herbaceous growth. The recovery of herbaceous vegetation after the 1972-73 drought in the Sahel was quicker where woody vegetation was present (Bernhardt-Reversat 1977). Walker and Noy-Meir conclude that
savanna is perturbed by climatic shifts, fire, grazing, and fuelwood consumption, which is reflected in the changes in relative proportions of grass and trees. However, theories on the mechanisms controlling savanna structure are hotly debated (Menaut 1983). The savanna structure, particularly the proportion of woody cover, is an important indicator of environmental conditions. Our canopy model will provide a method for measuring woody cover over large areas.

3.2. Savanna Vegetation of West Africa

The rainfall gradient is very steep in tropical and sub-tropical West Africa, about 1 mm/km latitude, and the rainy season is unimodal. The savanna bioclimatic regions are referred to as the Sahelian and Sudanian zones. This region is a vast plain, interrupted by some escarpments and massifs, but mostly composed of eroded sedimentary material and Pleistocene fossil dune systems. The plain is often internally drained into small depressions, and throughout the region there is an impermeable (often ferricrete) layer at varying depth and of varying thickness. These features control the local distribution of vegetation.

*Sahel* is an Arabic word meaning shoreline, and refers to the southern boundary of the Sahara desert. The Sahelian zone corresponds roughly to the 200-400 mm annual precipitation zone, and is further subdivided into:

- Saharo-Sahelian transition 100-200 mm
- Sahel proper 200-400 mm
- Sudano-Sahelian transition 400-600 mm

by Chevallier (1900), Aubréville (1949), Boudet (1975), Le Houerou (1980), Penning de Vries an Djiteye (1982), and Breman and de Wit (1983). The rainy season varies from 1.5 mos in the north to 3.5 in the south, from 20 rain days to 60, and the mean annual precipitation coefficient of variation ranges from 40 % to 25% (Tucker et al. 1985). The vegetation of the Sahel ranges from an open annual grassland (*Panicum turgidum, Cenchrus biflorus*), with less than 10% woody cover dominated by spiny trees and shrubs (*Acacia raddiana, Balanites aegyptica, Zizyphus*
mauritanica), in the north to perennial grasses with 25% or more tree cover (including Combretaceae — Combretum, Terminalia) in the south. The northern limit of the Sahel is sometimes defined by the absence of the grass Cenchrus biflorus ("kram-kram"). Basal area ranges from 4-16 m²/ha for the tree layer (Rutherford 1982), and annual production by woody plants of leaves, stems and twigs is 80-300 kg/ha/yr (Le Houerou 1980). The latitudinal trend in density of woody cover is modulated by topographic position and soil type (affecting moisture availability). For example, Acacia nilotica and A. seyal are locally dominant and dense in low, flooded areas, Euphorbia balsamifera is dominant in the northern Sahel where the impermeable ferricrust is close to the surface, and shallow gravelly slopes have a unique floristic association (the "Brousse tigre").

Leaf biomass can be predicted from stem circumference, tree height, or crown diameter \( (R^2 \approx .80-.96) \) (Cissé 1980a and b, Bille 1980). In the Sahel, green leaf biomass of woody species, and crown closure were shown to be proportional to mean annual rainfall and inversely proportional to herb cover (Cissé and Breman 1982). A study in the Sudan showed a strong correlation \( (R= .94) \) between woody biomass and crown diameter (Olsson 1984). Since the canopy model predicts average crown size and density, this bodes well for using the model to estimate biomass.

Phenology of trees and grasses is highly variable, and dependent of species and morphological differences, the presence of deep soil water, and so forth. However, many woody plants in the Sahel leaf at the end of the wet season, greening up as much as three months after the peak of herbaceous productivity (for example, Acacia senegal, Commiphora africana, Combretum micranthum, Euphorbia balsamifera, Guiera senegalensis and Zizyphus mauritiana; Poupon and Bille 1974). Other species have the opposite pattern, greening in the late dry season before the rains.

The Sudanian zone is the region to the south of the Sahel, lying between about 11° and 13° N in West Africa, where the rainfall is 600 to 1000 mm, the rainy season lasts 4 to 5 months, and there is permanent agriculture. The vegetation is a mosaic of open woodland savanna, up to about 15 m tall, some closed woodland, and edaphic bush thickets and grasslands on ferricrete
and inundated soils. Dominant woody species include *Vitellaria paradoxa*, *Acacia albida*, *Albizia chevallieri*, *Prosopis africana*, *Cassia seiberiana*, *Adansonia digitata* and *Parkia biglobosa*. The northern limit of the Sudanian zone is marked by the disappearance of *Vitellaria paradoxa* ("karite"), and *Adansonia digitata* (baobab) (Schnell 1977). This zone has been cultivated for a long time, with areas near villages under permanent cultivation, and bush fallowing practiced in fields further away. The crop/woodland or "orchard bush" type of vegetation is formed when crops are grown under a woodland of useful trees which are preserved when the land is cleared (Nielsen 1965).

All of these characteristics (open tree canopy, herbaceous understory, simple basal area/biomass relationship, woodland of continuously varying density, but complex spatial mosaic of physiognomic types) indicate that the stratification approach and the Strahler-Li canopy model will be applicable to this area, and provide a method for assessing woodland structure, and detecting and quantifying woody cover.

### 3.3. Sahelian Sites in Mali

A study is being conducted in the Gourma area of Mali by the Centre International pour l'Elevage en Afrique (CIPEA) (Pierre Hiernaux, Principal Investigator), in collaboration with the GIMMS (Global Inventory, Monitoring and Modeling System) Project at NASA/Goddard Space Flight Center. CIPEA has located thirty sites of 1 km radius along a north-south transect from near Douna in the south (14° 40' N, 1° 35' W, 500 mm annual ppt.), to Gourma-Rharous on the Niger River in the north (17° 45' N, 1° 50' W, 250 mm annual ppt.). These sites were chosen to be of relatively homogeneous vegetation and substrate (according to tone and texture on air photos) over an area of at least 1 km², for an AVHRR study (Hiernaux and Justice 1986).

In the first year we are testing the canopy model in CIPEA Sites 15 (near Gossi), 20 and 21 (near Hombori — see Figure 3). Site 15 is located in an *Acacia nilotica* woodland (approximately 30 percent cover), with an understory of predominantly *Echinochloa colonna* on an alluvial plain of poorly drained vertisols. Part of this stand can remain flooded throughout the dry season.
Site 20 is located in an *Acacia seyal* woodland (approximately 57% cover), with 47 percent herbaceous cover (*Echinochloa, Sporobolis helvolis, and Corchorus tridens*), also on an alluvial plain of vertisols, that is inundated during the rainy season, but more freely drained that Site 15 (Hiernaux et al. 1984). Site 21 is very similar to Site 20, with woody cover approximately 44 percent, predominantly *Acacia seyal* (personal observation and P. Hiernaux 1985, unpublished data).

### 3.4. Sudanian Sites in Mali

The Sudanian test sites are in the Region of Ségou, between Tamani and Konodimini (6° 50' W and 6° 20' W) and the Niger River and Nango (13° 25' N and 13° 10' N). This area is being used by R. Cole (Department of Geography, Michigan State University), in his study of the changes in land use practices in response to the drought since the early 1970's. Rainfed crops are grown during the two to three month growing season under a canopy of preserved trees (predominantly *Vitellaria paradoxa, Acacia albida, Adansonia digitata, Ficus sp., Tamarindus indica, and Parkia biglobosa*). In November 1985 measurements were taken at four sites in the Region of Ségou (Figure 4). Sites 1 and 2 are dominated by *Vitellaria paradoxa*, and are located southwest and east of Konodimini respectively, in the house fields (cultivated areas near the village where shrubs and weeds are cleared regularly). Sites 3 and 4 are dominated by *Acacia albida*, and are located in the house fields surrounding the villages of Massala and Dugufé. *Acacia albida* has a characteristic distribution pattern in this area. It was planted in antiquity, and is preserved near villages. It dominates within a distance of 0.5 km of the village perimeter with crops grown beneath. Beyond that distance, karité dominates where there is cultivation.
4. METHODS

4.1. Pattern Analysis

The purpose of pattern analysis is to explore the temporal and spatial patterns of the imagery and the ground scene in order to guide the choice of stratification techniques. Recent work (Woodcock and Strahler 1983, Woodcock 1986) shows that spatial pattern in multi-spectral scanner imagery is dependent on scale, and the spatial characteristics of the scene elements within a particular information class or cover type. Two-dimensional variograms will be calculated (see Woodcock 1986) for test areas of different known vegetation types in the image data. The expected result is a description of the spatial variance of tones in the images, which will indicate the relative scales of pattern, and provide a basis for choosing an appropriate texture measure, or describing the image context function, for possible use in the segmentation step.

Many researchers have attempted to understand and describe the pattern of vegetation in the woodland/grassland/shrubland complex of west Africa and there is no simple deterministic model of the spatial and temporal distribution of vegetation in this or any area with a long and complex land use history. However, it may be possible to include information about vegetation spatial pattern in the information extraction process, at least empirically.

4.2. Image Stratification

The purpose of image stratification (or segmentation) is to identify areas of woodland in the image, and stratify the area into woodland stands of some minimum area which are of relatively homogeneous density. This task has been successfully accomplished in prior research (Franklin et al. 1985, Strahler et al. 1983) by using MSS, image texture and digital terrain data, carrying out unsupervised classification, then subsequently performing spatial filtering to produce spatially homogeneous stands.

For the present study terrain data will not be used. It is not available, and would be marginally useful in this environment for discriminating vegetation types. We will use two-date TM
imagery (one wet season and one dry season image), and possibly a texture image (Zhan 1986) as input to unsupervised classification. Principal components images, either from each date, or both dates combined, could be used to reduce the number of data channels used in classification. We anticipate that with two-date, well-registered images, the cover types can be discriminated spectrally, possibly with the help of a texture measure. The classification will be evaluated using standard accuracy assessment procedures for thematic maps (Rosenfeld et al. 1982, Card 1982), and by the ability of the stratification to reduce variance in cover estimates or basal area within woodland strata.

An alternative approach is to use a per-field (Latty and Hoffer 1981) or contextual (Tilton et al. 1983) classification technique that incorporates spatial information into the classification step. Contextual classification will probably not be useful in this environment because the cover classes do not have simple, deterministic, invariant spatial patterns.

In their current research activities, Li and Strahler are exploring the feasibility of modifying the canopy model so that it can be applied to each pixel using a moving window. However, this approach assumes that the Poisson parameter is stationary within the window, and is therefore suitable only for forests or woodlands without abrupt vegetation boundaries. This simplifies the stratification problem to identifying areas of more or less continuous woodland within which the moving window can be applied, so that a simple edge detection algorithm could be used for image segmentation. The moving-window extension would thus make the model more powerful and flexible in a natural environment where woody cover density is continuously varying. If their extension is successful, a moving-window approach will be used. Otherwise, the variance dependent model will be applied to a stratified image.

4.3. Canopy Reflectance Modeling

The tree cover in savanna wooded grassland is sufficiently sparse that the overlapping of shadows and crowns should not be a significant problem and the simple variance dependent model can be applied. The following assumptions must be modified from those presently used in the
Strahler-Li model:

1. **tree shape**: A semisphere on a stick, inverted cone, or disc on a stick model for tree shape will be appropriate for Sahelian and Sudanian savannas. None of these shapes poses a significant problem for incorporation into the invertible model -- they simply modify the estimated proportions of green canopy, dark shadow, and understory in a pixel. Li and Strahler have extended the model for these shapes (Figure 1). The ratio of height to crown diameter will be established from test data.

2. **height distribution**: Field measurement of height distribution, will be very important in the Sahelian and Sudanian zones where extensive measurements of these parameters do not exist.

3. **spatial distribution**: Our earlier research (Strahler and Li 1981, Franklin 1983) has shown that it is possible to estimate the spacing parameters of the model from medium-scale air photos. The ability to describe spatial pattern from air photos in Mali must also be verified by field measurements of pattern.

4. **component spectral signatures**: Sensitivity analysis of the Li-Strahler model shows that the larger the difference between the Background and Tree-Shadow signatures, the stabler the results. If a projection can be chosen in spectral space which maximizes spectral separability of the components, this will minimize error. Also, as each tree has a bigger impact (as the sun angle, and therefore the amount of shadow increases) the results are more stable. When trees are small or sparse, the above factors are more important than noise in the tree signature, or in the shape parameter. This makes intuitive sense — when the amount of “tree-ness” in the pixel is low, the model is more sensitive to variations in the background signal than the tree signal.

Therefore, the natural variability of the tree population in terms of shape and spectral properties, will not cause significant errors on the model results, but variations in the background signature will. A projection can be chosen in spectral space which minimizes variations in background signature. Because of variations in the background, it may be difficult to characterize the Tree/Shadow signature with training data. We will use several
training fields with different backgrounds and known tree density, and take an average spectral signature.

(5) tree size and density for test stands: In order to verify model results, tree size and density will be sampled in test stands.

4.4. Work in Progress

Image and Collateral Data

Thematic Mapper data for the study areas have been acquired. Geometrically corrected P-Tapes were purchased from EOSAT. For the Gourma test sites a scene was chosen from the late part of the growing season (9 September 1984). The scene is #5019209552, WRS Path 195, Row 49 (Quadrant 3), which includes the sites from north of Gossi to south of Hombori (Sites 14 to 21 and 31, see Figure 3). This date was chosen because it coincided with CIPEA field data collection. However, this scene is not optimal for discriminating trees from herbaceous understory, because there were several September rainfall events in 1984, and in this image the herbaceous vegetation is still green in the wetter sites (e.g., Site 15) and in some areas of the dunes. Therefore, a late dry season image (7 May 1985) has been ordered, to use for multi-date stratification, and for testing the canopy model in contrasting seasons. For the Region of Ségou, a post-harvest, early dry season image (17 November 1984) was acquired (Scene #5026110142, Path 198, Row 51).

Topographic maps at several scales (1:200,000 and 1:1,000,000) were acquired for both the Gourma and Ségou sites. Black and white aerial photographs are available for the Republic of Mali at a scale of 1:60,000, but they date from 1956. These are the only small-scale photographs available in the Gourma area, and will be required for image registration, location of study sites, strata labeling, and so forth. Therefore, partial coverage for the Gourma area was acquired. In the Region of Ségou, 1:50,000 black and white panchromatic photos from 1974 are available for part of the region due to the presence of "Projet Riz" (an extensive irrigation project for rice
Annual Report NASA Award NAGW-788

growing) in this area. These photos have been purchased. Current (1985-1986) low-level color air photos (1:2500 to 1:5000 scale) for some of the study sites in both regions were made available to us by CIPEA. All of these maps and photo data sources will be used for locating study sites, model parameterization (calculating tree spatial pattern and measuring density and cover for sample stands to be used in accuracy assessment), image registration (to help interpret from satellite imagery to topographic maps) and strata labeling during the image stratification step.

Field Data Collection

In the Gourma sites the CIPEA team has estimated woody cover by the line intercept method, and estimated tree height, circumference, and crown area for the trees intercepted by the one kilometer transect. We have received the tree cover and dimensional data from CIPEA so that the distribution of tree sizes can be established for the sites, and cover estimates can be used to verify model results. Also, in an earlier study (Cisse' 1980b) stratified (by diameter class) samples of several dominant Sahelian woody plants were measured to establish the dimensional relationships among height, stem diameter and crown diameter. These data were used to establish the shape parameter (\(\alpha\)) for the model.

In the Ségou region, four 50 to 60 m radius plots were located in each of the four sample stands. Diameter at breast height (dbh) of each tree, and height and shape parameters for a subsample of the trees (16 trees per plot) were measured. From these measurements the shape parameter and the size distribution for the stands were estimated.

Analysis of Aerial Photographs

Using the low altitude CIPEA photographs of the training sites, we have mapped tree point pattern in two Gourma and two Ségou sites. In 280 x 280 m, 250 x 250 m or 140 x 140 m quadrats 200 to 900 trees per quadrant were located. Spatial pattern has been analyzed using quadrat analysis (Li and Strahler 1981; Franklin et al. 1985, from Grieg-Smith 1964 and Pielou 1977), and second order analysis of inter-tree distances (Franklin and Getis 1985, Getis and Franklin 1986).
We have also sampled density and tree cover for the quadrats by the dot grid method (Warren and Dunford 1983), to assess the accuracy of the model.

**Image Processing**

**Registration and Subimage Selection:** The Thematic Mapper data were registered to a map base using about 30 control points per quarter scene, and the IDIMS software at NASA Goddard. TM P-Tapes are geometrically corrected, and we probably did not improve on the geometric accuracy of the data using 1:200,000 topo maps, ephemeral streams as control points and nearest neighbor resampling. Therefore, we have decided to use the un-registered data for testing the model, and use the derived polynomial transforms for registering the stratified image if necessary.

**Principal Components Images:** Principal components images were produced for each subimage separately from six TM spectral bands (not including the thermal channel because of the lower spatial resolution). Principal components images can be used as input to image stratification and canopy model testing (see below).

**Image Stratification:** The method used for image stratification is unsupervised clustering, classification, and cluster labeling. A small test area (256 x 256 pixels) was chosen in each subimage, and classification and clustering were performed both on principal components (PC) images and TM spectral bands. Spectral classes were inspected to determine if TM or PC images better discriminated the land cover classes in these areas.

**Stand and Component Signatures:** The mean and variance of the reflectance in each spectral band were computed for the test sites (these make up the vector S). The spectral signatures of the model components must also be calculated. Background signature can be assigned from training sites. Tree plus associated shadow signature can be estimated in two ways. For sites where there are cover measures in plots that can be located in the image, spectral brightness will be regressed against cover, and extrapolate to 100 percent cover. For the other sites, unsupervised spectral clustering of the spectral data within the site will be performed, assuming that the "darkest" class has the cover density measure by CIPEA. The co-spectral plot of red and near infrared
reflectance (or greenness and brightness) will be inspected, and we will assume that brightness
decreases and greenness increases linearly with cover.

Testing the Model

Model inversion will be tested for single and multiple spectral bands (or transformed spectral data — principal components). The parameters needed to calculate to test the simple model are the component signatures, $G$ and $X_0$, the shape parameter $\alpha (= \frac{r}{h})$, and $CV(R^2)$. The cosine of the solar zenith angle was calculated for each image based on the date and local time of the overpass, and the latitude and longitude of the scene center, using a program written by Jeff Dozier. The simple model will be tested using programs written by Li Xiaowen.

We will test the model for two spatial scales, by resampling TM data to MSS resolution. The model is most cost-effective when applied at the coarsest resolution for which it produces reasonably accurate results. Franklin (1983) has shown that stand density varies more as spatial resolution increases. This may make model inversion more difficult, by making it harder to characterize the spatial pattern of the trees with a simple statistical model. However, Strahler and Li (1981) were able to successfully apply the model in their small test area using a two-parameter (double Poisson) model of tree spatial pattern, at 80 m MSS resolution.
5. RESULTS

5.1. Canopy Model

5.1.1. Tree Shape and Allometry

The tree shape parameter for a semisphere model, $\alpha = h/r$, the ratio of stem height to crown width, was calculated empirically from sample data for each study site, and from other studies, for five tree species (Tables 1 and 2). In this study each of these species dominated in the sites where they were found, making up over 80% of the crown cover. The shape parameter varies from 0.5 to 1.7, with most values falling between 0.7 and 1.5. From this shape parameter and the sun angle at the time of the Landsat overpass, $\Gamma$ was calculated for input to the simple model (Table 3).

Table 4 shows the allometric relationships among crown radius (or diameter, or surface area), stem diameter (or circumference) and height. The $R^2$ values for the stratified (by size class) samples (from Cissé 1980 b) are improved over the values for the larger random samples (from Hiernaux et al. 1984 and this study) but are more representative of the predictive power of these relationships. The stratified sample more closely approximates a Model I regression (see Sokal and Rohlf 1969), where the independent variable is under investigator control.

5.1.2. Tree Size Distribution

Histograms of each of the sample populations were inspected to determine the shape of the size distributions. Histograms of crown size, height and stem size were examined, and because of the intercorrelation of these measurements (see last section) the shape of the distributions were similar. A lognormal distribution of tree size describes most of the sample populations. The distributions were right-skewed and a log transform of the data produced a normal looking distribution (Fig. 5). Therefore, a lognormal distribution will be used in testing the canopy model, with the parameter $CV(R^2)$ (coefficient of variation of the average squared crown radius) derived from
the sample populations (see Table 2).

5.1.3. Spatial Pattern

Figure 6a shows the tree point locations for Gourma Site 20 as an example of the data set used to calculate spatial pattern. The results of second order analysis (Getis 1984, Franklin et al. 1985 and Getis and Franklin 1986) for sample quadrats in the test sites are as follows:

**Gourma Site 20:** \((n = 895, 280 \times 280 \text{ m quadrat})\) There is significant inhibition (at 1% level) at 6 to 7 m distance, and significant (at 5% level) clumping at 30 to 100 m (Figure 6b), but the pattern looks very regular, and the aggregation found by this method contradicts the results of the quadrat analysis (see below).

**Gourma Site 15:** \((n = 589, 280 \times 280 \text{ m quadrat})\) There is significant (at 1% level) inhibition (regular spacing) at less than 5 m distance, and significant (at 5% level) clumping at 20 m and 100 m. At 25 to 80 m distance (satellite scanner resolution) the Poisson model (or Complete Spatial Randomness) is adequate (Fig. 7b).

**Ségou Site 2:** Subplot 1: \((n = 222, 250 \times 250 \text{ m quadrat})\) Inhibition to 8 m, Poisson model adequate from 9 to 50 m, significant aggregation from 60 to 100 m (at 1% level). Subplot 2: \((n = 228, 250 \times 250 \text{ m quadrat})\) Inhibition to 8 m, Poisson model fits from 10 to 26 m and 36 to 100 m, significant aggregation at 28 to 34 m (at 5% level) (Fig. 8).

Figure 7a shows the point locations for trees in Gourma Site 15 with a 30 m grid overlain, to illustrate how counts of trees would vary in TM-sized pixels. The results of variable sized quadrat analysis (Franklin et al. 1985) are shown in Table 5. Gourma Site 20 is fit by a Poisson model for quadrats of size 20 to 35 m, but not 40 m. This is partly a function of decreased sample size. Gourma Site 15 is fit by a Poisson model for quadrats of size 20 to 50 m, except that counts in 30 m quadrats differ significantly from Poisson. Ségou Site 2 (Subplot 1) is fit by a Poisson model for quadrats of size 10 to 60 m. It was not possible to test by this method for larger quadrats because of the size of the sample areas.
Our conclusion from these preliminary analyses of some of the sample sites is that a random (Poisson) spatial model is adequate at relevant sensor resolution of 20 to 50 m pixels. At coarser resolution, second order analysis shows the Poisson model to be adequate at distances of 50 to 100 m in most cases, including the sparser stands (Ségou Site 2) where our earlier studies show that the Poisson model breaks down (Franklin et al. 1985).

5.1.4. Accuracy

In order to assess the accuracy of the simple canopy model, an independent measure of tree size and density for the sites is needed. Table 6 shows estimates of tree size and density based of field and photogrammetric sampling.
6. SUMMARY

6.1. Anticipated Problems

We have discussed the strengths of the canopy modeling approach, and explained why we think it will be successful. Now we would like to discuss its weaknesses, the problems we anticipate, and how we will address them.

(1) Characterization of component signatures may be a problem, particularly background signature, which the model is sensitive to, and which is highly variable in this region. Image stratification will help reduce this problem — background signature can be assigned empirically within strata. In other words, there may be two strata of the same woodland density class, but with different background signatures.

(2) Transmission of light through the canopy may not be negligible, particularly in Sahelian *Acacia* woodland (S. Prince, personal communication, personal observation). This can be addressed by adding a transmissivity correction derived empirically from field measurements, the literature, calculated from another model of tree reflectance (Kimes 1986), or calculated from this model, as Li and Strahler (1985) did. Also, spectral bands on transforms can be chosen that de-emphasize transmissivity. Likely candidates are visible bands or brightness transforms — the canopy transmits more near-infrared than visible light.

(3) The highly variable phenology of the herbaceous (understory) and tree layer may make it difficult to apply this model over large areas, or on a repetitive basis as a monitoring technique. Greening up of grasses and leafing out of trees can occur locally (in time or space) in response to rainfall events. This is more of a problem in the Sahelian zone. Also in the Sahelian zone, although the leafing of trees lags behind greening of grasses for most species or vegetation types (trees remain green for at least part of the dry season) there is overlap, and particularly in the inundation zones where tree cover is densest, and signature discrimination between trees and background may be difficult. This can be addressed in the second year when multi-date imagery can be used for signature definition, as well as stratification.
Annual Report NASA Award NAGW-788

(4) Most of the Sahelian zone has extremely low woody cover. An important question will be what the lower density limits of the model are — when does the tree signal get lost in the noise of background variation? Trees can be identified of high resolution air photos at very low density (2-3%), but can they in satellite imagery, using the model?

(5) Signature and parameter extension — How generalizable are the parameters of the model in this environment? Can the same shape, size distribution and pattern parameters for trees be extrapolated to other stands in the same strata, and over how great a biogeographic range? At what spatial scale does an atmospheric variation affect the accuracy of the model? If the model parameters are very site-specific, then its inversion is theoretically interesting, but not very practically applicable. This will be addressed in the second year, when the model will be tested in new sites outside of the training sites.

6.2. Discussion

By modifying and extending an invertible canopy reflectance model to tropical savanna, we anticipate the following results:

(1) Through exploration of the reflectance model, an improved understanding of the interaction between land surface, radiation, and sensor, particularly the effects of scale-dependent patterns and architecture of the objects in the scene.

(2) Through application of the model using Landsat imagery, an improved ability to extract information on biophysical parameters of the land from remotely sensed data.

(4) Through field measurements required for modeling, cooperation with ongoing intensive field investigations, and by applying remotely sensed data as an additional measurement tool, an improved understanding of the structure, distribution and dynamics of the savanna ecosystem.

This last point has implications at both regional and global scales. An increase in the fundamental knowledge of the factors underlying vegetation distribution will provide basic input for planning at a regional level in an area that is under extreme human population pressure. Also this
study will provide information presently lacking on the temporal and spatial dynamics of savanna ecosystems for input into global ecological and climatological models. We anticipate that through functionally relating physiognomic and physiographic pattern on the landscape to image spatial and temporal pattern, a previously underexploited layer of data can be added to the process of information extraction from multiresolution, multitemporal, and multispectral remotely sensed data.
