Abstract

Improvements to a time-accurate approximate factorization (AF) algorithm have been implemented for steady and unsteady transonic analysis of realistic aircraft configurations. These algorithm improvements have been made to the CAP-TSD (Computational Aeroelasticity Program - Transonic Small Disturbance) code developed recently at NASA Langley Research Center. The code permits the aeroelastic analysis of complete aircraft in the flutter critical transonic speed range. The AF algorithm of the CAP-TSD code solves the unsteady transonic small-disturbance equation. The algorithm improvements include: an Engquist-Osher (E-O) type-dependent switch to more accurately and efficiently treat regions of supersonic flow, extension of the E-O switch for second-order spatial accuracy in these regions, nonreflecting far field boundary conditions for more accurate unsteady applications, and several modifications which accelerate convergence to steady-state. Calculations are presented for several configurations including the General Dynamics one-ninth scale F-16C aircraft model to evaluate the algorithm modifications. The modifications have significantly improved the stability of the AF algorithm and hence the reliability of the CAP-TSD code in general. The paper presents detailed descriptions of the algorithm improvements along with results and comparisons which demonstrate the improved stability, accuracy, and efficiency of the CAP-TSD code.

Nomenclature

c = airfoil chord
Cμ = unsteady lift-curve slope
C_r = wing reference chord
\( \rho \) = pressure coefficient
k = reduced frequency, \( \omega c/2U \)
M = freestream Mach number
NSUP = number of supersonic points
R = residual
\( t \) = time, nondimensionalized by freestream speed and wing reference chord
\( U \) = freestream speed
\( \alpha \) = instantaneous angle of attack
\( \alpha_0 \) = mean angle of attack
\( \alpha_1 \) = amplitude of pitch oscillation
\( \gamma \) = ratio of specific heats
\( \delta t \) = nondimensional time step
\( \eta \) = fractional semispan
\( \phi \) = disturbance velocity potential
\( \omega \) = angular frequency

Subscript

t = tail
w = wing

Introduction

Presently, considerable research is being conducted to develop finite-difference computer codes for calculating transonic unsteady aerodynamics for aeroelastic applications. These computer codes are being developed to provide accurate methods of calculating unsteady airloads for the prediction of aeroelastic phenomena such as flutter and divergence. For example, the CAP-TSD2 unsteady transonic small-disturbance (TSD) code was recently developed for transonic aeroelastic analyses of complete aircraft configurations. The name CAP-TSD is an acronym for Computational Aeroelasticity Program - Transonic Small Disturbance. The new code permits the calculation of unsteady flows about complete aircraft for aeroelastic analysis in the flutter critical transonic speed range. The code can treat configurations with arbitrary combinations of lifting surfaces and bodies including canard, wing, tail, control surfaces, tip launchers, pylons, fuselage, stores, and nacelles. In Ref. 2, steady and unsteady pressures were presented for several complex aircraft configurations which demonstrated the geometrical applicability of CAP-TSD. These calculated results were in good agreement with available experimental pressure data which validated CAP-TSD for multiple component applications with mutual aerodynamic interference effects. Preliminary aeroelastic applications of CAP-TSD were presented in Ref. 3 for a simple well-defined wing case. The case was selected as a first step toward performing aeroelastic analyses for complete aircraft configurations. The calculated flutter boundaries compared well with the experimental data for subsonic as well as supersonic freestream Mach numbers, which gives confidence in CAP-TSD for aeroelastic prediction.

The CAP-TSD code uses a time-accurate approximate factorization (AF) algorithm recently developed by Batina for solution of the unsteady TSD equation. The AF algorithm involves a Newton linearization procedure coupled with an internal iteration technique. In Ref. 4, the algorithm was shown to be efficient for application to steady or unsteady transonic flow problems. It can provide accurate solutions in only several hundred time steps, yielding a significant computational cost savings when compared to alternative methods. For reasons of practicality and affordability, an efficient algorithm and a fast computer code are requirements for realistic aircraft applications.

The purpose of this paper is to describe recent changes to the CAP-TSD code which have significantly improved the stability of the AF algorithm and the accuracy of the results. The algorithm modifications include: (1) improved type-dependent differencing to treat regions of supersonic flow, (2) extension of the type-dependent differencing for second-order spatial accuracy, (3) nonreflecting far field boundary conditions for unsteady applications, and (4) several modifications to accelerate convergence to steady-state. The paper presents detailed descriptions of these algorithm improvements along with results and comparisons which assess the improved stability, accuracy, and efficiency of the CAP-TSD code.

**Algorithm Improvements**

**Engquist-Osher Type-Dependent Switch**

Algorithms based on the TSD equation typically use central differencing in regions of subsonic flow and upwind differencing in regions of supersonic flow. This, of course, allows for the correct numerical description of the physical domain of dependence. The original CAP-TSD code of Ref. 2 used the Murman type-dependent switch to change the spatial differencing. The Murman switch, however, admits nonphysical expansion shocks as a part of the solution and has been shown to be less stable than monotone methods. For example, unsteady results for a NACA 64A006 airfoil were presented in Ref. 7 which demonstrated an order of magnitude increase in time step using a monotone algorithm. Therefore, an Engquist-Osher (E-O) monotone switch, similar to that of Ref. 6, has been incorporated within the AF algorithm of the CAP-TSD code. The E-O switch is based on sonic reference conditions and does not admit expansion shocks as part of the solution. Use of the E-O switch also generally increases computational efficiency because of the larger time steps which may be taken. Mathematical details of the required algorithm changes are described in a subsequent section.

**Second-Order Accurate Spatial Differencing**

Most TSD algorithms are only first-order-accurate spatially in regions of supersonic flow. This is due to the first-order upwind differencing that is typically used to treat these regions. Use of second-order upwind differencing has been shown to improve the accuracy of the solution while retaining the numerical stability of the first-order method. Consequently, the E-O type dependent switch of the AF algorithm has been extended for second-order spatial accuracy in supersonic regions of the flow. Comparisons of results obtained using first-order and second order differencing, to be presented, demonstrate the improved accuracy of the second order method.

**Nonreflecting Far Field Boundary Conditions**

For unsteady applications, the far field boundary conditions can have a significant influence on the accuracy of the solution. Steady state boundary conditions are inadequate for unsteady calculations, since disturbances reaching the boundaries are reflected back into the computational domain. These reflected disturbances can propagate into the near field and thus produce inaccurate results. One solution to this problem is to locate the grid boundaries far away to minimize the effect of the boundary conditions. This is generally not an acceptable remedy because of the higher computational cost which results from an increased number of grid points required to discretize a larger computational domain. The more appropriate solution is the use of nonreflecting far field boundary conditions which absorb most of the waves that are incident on the boundaries and consequently allow the use of smaller computational grids.

Nonreflecting boundary conditions similar to those of Whitlow have been incorporated within the CAP-TSD code. These boundary conditions are consistent with the AF solution procedure and are described in more detail below. Results obtained with and without the nonreflecting boundary conditions are presented which demonstrate their effectiveness.

**Steady-State Convergence Acceleration**

Finally, several algorithm changes have been made to accelerate convergence to steady-state. Besides the E-O switch, these changes include: (1) deletion of the time-dependent terms from the residual of the AF algorithm, (2) deletion of all of the time-derivatives of the TSD equation, and (3) over-relaxation of the residual. The effects of each of these modifications on the steady-state convergence are demonstrated in the results presented herein.

**Transonic Small-Disturbance Equation**

The flow is assumed to be governed by the general frequency modified TSD potential equation which may be written in conservation law form as

$$\frac{\partial \phi_0}{\partial t} + \frac{\partial \phi_1}{\partial x} + \frac{\partial \phi_2}{\partial y} + \frac{\partial \phi_3}{\partial z} = 0$$

where

$$\phi_0 = -A \phi_1 \cdot B \phi_2$$

$$\phi_1 = E \phi_2 + F \phi_3$$

$$\phi_2 = G \phi_4 + H \phi_3 \phi_4$$

The coefficients A, B, and E are defined as

$$A = M^2, \quad B = 2M^2, \quad E = 1 \cdot M^2$$

Several choices are available for the coefficients F, G, and H depending upon the assumptions used in deriving the TSD equation. The coefficients are herein defined as

$$F = \frac{1}{2} (\gamma + 1) M^2$$

$$G = \frac{1}{2} (\gamma - 3) M^2$$

$$H = \gamma (\gamma - 1) M^2$$

**Approximate Factorization Algorithm**

An approximate factorization algorithm was developed to solve the modified TSD equation (Eq. (1)). In this section, the AF algorithm is described.

**General Description**

The AF algorithm consists of a Newton linearization procedure coupled with an internal iteration technique. For unsteady flow calculations, the solution procedure involves two steps. First, a time linearization step (described below)
is performed to determine an estimate of the potential field. Second, internal iterations are performed to provide time accurate modeling of the flow field. Specifically, the TSD equation (Eq. (1)) is written in general form as

$$R(\phi^{n+1}) = 0$$  \hspace{0.5cm} (5)

where $\phi^{n+1}$ represents the unknown potential field at time level $(n+1)$. The solution to Eq. (5) is then given by the Newton linearization of Eq. 5 about $\phi^*$

$$R(\phi^*) + \left( \frac{\partial R}{\partial \phi} \Big|_{\phi=0} \right) \cdot \Delta \phi = 0$$  \hspace{0.5cm} (6)

In Eq. (6), $\phi^*$ is the currently available value of $\phi^{n+1}$ and $\Delta \phi = \phi^{n+1} - \phi^*$. During convergence of the iteration procedure, $\Delta \phi$ will approach zero so that the solution will be given by $\phi^{n+1} = \phi^*$. In general, only one or two iterations are required to achieve acceptable convergence. For steady state calculations, iterations are not used since time accuracy is not necessary when marching to steady-state.

**Mathematical Formulation**

The AF algorithm is formulated by first approximating the time derivative terms ($\partial t$ and $\partial x$) terms) by second-order accurate finite-difference formulae. The TSD equation is rewritten by substituting $\phi = \phi^* + \Delta \phi$ and neglecting squares of derivatives of $\Delta \phi$ which is equivalent to applying Eq. (6) term by term. The resulting equation is then rearranged and the left-hand side is approximated factored into a triple product of operators yielding

$$L_\zeta L_\eta L_\zeta \Delta \phi = - \alpha R(\phi^*, \phi^1, \phi^2)$$  \hspace{0.5cm} (7)

where

$$L_\zeta = 1 + \frac{3R}{4A} \cdot \frac{\Delta \phi}{\Delta z} \cdot \frac{\Delta z}{2A} \cdot \frac{\Delta z}{\Delta z} = \frac{1 + \frac{3R}{4A}}{\frac{\Delta \phi}{\Delta z} + \frac{\Delta z}{2A} + \frac{\Delta z}{\Delta z}}$$  \hspace{0.5cm} (8a)

$$L_\eta = 1 + \frac{\Delta \phi}{\Delta \eta} \cdot \frac{\Delta \eta}{2A} = \frac{1 + \frac{\Delta \phi}{\Delta \eta}}{\frac{\Delta \eta}{2A}}$$  \hspace{0.5cm} (8b)

$$L_\zeta = 1 + \frac{\Delta \phi}{\Delta \zeta} \cdot \frac{\Delta \zeta}{2A} = \frac{1 + \frac{\Delta \phi}{\Delta \zeta}}{\frac{\Delta \zeta}{2A}}$$  \hspace{0.5cm} (8c)

$$F_1 = E\xi_x^{\phi^*} + 2F\xi_y^{\phi^*} + 2G\xi_y^{\phi^*} \cdot (\xi_y^{\phi^*} + \phi^*)$$

$$+ \xi_x^{\phi^*} (1 + H\xi_x^{\phi^*}) + H\xi_y^{\phi^*} \cdot (\xi_y^{\phi^*} + \phi^*)$$  \hspace{0.5cm} (8d)

$$R = -\xi \left( \frac{E}{2A} \cdot \frac{\Delta \phi}{\Delta z} \cdot \frac{\Delta z}{2A} \cdot \frac{\Delta z}{\Delta z} \right) + \frac{\partial}{\partial \zeta} \left( \frac{\Delta \phi}{\Delta \zeta} \cdot \frac{\Delta \zeta}{2A} \cdot \frac{\Delta \zeta}{\Delta \zeta} \right)$$

$$+ \frac{\partial}{\partial \eta} \left( \frac{\Delta \phi}{\Delta \eta} \cdot \frac{\Delta \eta}{2A} \cdot \frac{\Delta \eta}{\Delta \eta} \right) \cdot B \cdot $$  \hspace{0.5cm} (8e)

$$F_2 = \frac{1}{\xi_x} \cdot (1 + H\xi_x^{\phi^*})$$  \hspace{0.5cm} (8f)

$$F_3 = \frac{1}{\xi_x}$$  \hspace{0.5cm} (8f)

In Eq. (7), $\sigma$ is a relaxation parameter which is normally set equal to 1.0. To accelerate convergence to steady-state, the residual $R$ may be over relaxed using $\sigma > 1$. Equation (7) is solved using three sweeps through the grid by sequentially applying the operators $L_\zeta$, $L_\eta$, and $L_\zeta$ as

$$\zeta \cdot \text{sweep: } L_\zeta \Delta \phi = - \sigma R$$  \hspace{0.5cm} (9a)

$$\eta \cdot \text{sweep: } L_\eta \Delta \phi = \Delta \phi$$  \hspace{0.5cm} (9b)

$$\zeta \cdot \text{sweep: } L_\zeta \Delta \phi = \Delta \phi$$  \hspace{0.5cm} (9c)

Further details of the algorithm development and solution procedure may be found in Ref. 4.

**Engquist-Osher Type-Dependent Switch**

An Engquist-Osher type-dependent mixed difference operator has been implemented in the AF algorithm to treat supersonic regions of the flow. The E-O switch is based on sonic reference conditions and is applied to both sides of Eq. (7). For example, in the residual (Eq. (8g)) the terms that are upwind biased at supersonic points are defined by

$$\eta \cdot \text{sweep: } L_\eta \Delta \phi = \Delta \phi$$  \hspace{0.5cm} (9b)

$$\zeta \cdot \text{sweep: } L_\zeta \Delta \phi = \Delta \phi$$  \hspace{0.5cm} (9c)
Similar modifications to the left-hand side of Eq. (7) result
in a pentadiagonal system of equations for subsonic flows with
embedded supersonic regions and a tridiagonal system of
equations for purely subsonic flows. Furthermore, the
treatment of the $\phi_x$ term in the TSD equation is only first-
order accurate in space because of the one-sided differencing
used. Similar to Ref. 8, the $\phi_x$ term is backward differenced
to enhance diagonal dominance and consequently maintain
numerical stability.

\section*{Boundary Conditions}

\textbf{Flow-tangency.} - The flow tangency boundary
conditions are imposed along the mean plane of the respective
lifting surfaces and the wakes are assumed to be planar
extensions from the trailing edges to the downstream
boundary of the finite-difference grid. The numerical
implementation of these conditions\textsuperscript{2} allows for coplanar as
well as non-coplanar combinations of horizontal (canard,
wing, horizontal tail, launchers) and vertical (pylons,
vertical tail) surfaces. Bodies such as the fuselage, stores,
and nacelles are treated using simplified boundary anditions
on a prismatic surface rather than on the true surface.\textsuperscript{2} The
method is consistent with the small-disturbance
approximation and treats bodies with sufficient accuracy to
obtain the correct global effect on the flow field without the
use of special grids or complicated coordinate
transformations.

\textbf{Far Field.} - The conditions imposed upon the outer
boundary of the computational region are similar to the
nonreflecting boundary conditions reported by Whitlow.\textsuperscript{9}
The conditions employed here are given by

\begin{align}
\text{Upstream:} & \quad \phi = 0 \quad (13a) \\
\text{Downstream:} & \quad \frac{1}{2} B \phi_i + \frac{D}{\sqrt{C}} \phi_i + \phi_i = 0 \quad (13b) \\
\text{Above:} & \quad \frac{D}{\sqrt{C}} \phi_i + \phi_i = 0 \quad (13c) \\
\text{Below:} & \quad \frac{D}{\sqrt{C}} \phi_i + \phi_i = 0 \quad (13d) \\
\text{Right spanwise:} & \quad \frac{D}{\sqrt{C}} \phi_i + \phi_i = 0 \quad (13e) \\
\text{Left spanwise:} & \quad \frac{D}{\sqrt{C}} \phi_i + \phi_i = 0 \quad (13f) \\
\text{(for full-span modeling)}
\end{align}

\begin{align}
\text{Symmetry plane:} & \quad \phi_i = 0 \quad (13g) \\
\text{(for half-span modeling)}
\end{align}

In Eqs. (11) the $j$ and $k$ subscripts corresponding to the
spanwise and vertical directions, respectively, have been
omitted for clarity. Similar differencing is used on the left-
hand side of Eq. (7) where the first two terms of $F_1$ (Eq. 8d)
are upwind biased at supersonic points.

\section*{Second-Order-Accurate Spatial Differencing}

The AF algorithm with the E-O switch as defined by Eq.
(10) is only first-order accurate in supersonic regions of
the flow. To achieve second-order accuracy at supersonic as
well as subsonic points, Eq. (10) is extended as

\begin{align}
\frac{\partial}{\partial \xi} (E \xi \phi_i + F \xi^2 \phi_i) = & \Delta \xi f_{i+1/2} + \Delta \xi f_{i-1/2} \\
& + \Delta \xi \delta \xi_{i+1/2} \Delta \xi f_{i+1/2} \quad (12)
\end{align}

where

\begin{align}
\tilde{f}_{i+1/2} = & \bar{F} u_{i+1/2} + \bar{F} u_{i+1/2} \\
\tilde{f}_{i+1/2} = & \bar{F} u_{i+1/2} + \bar{F} u_{i+1/2} \\
\Delta \xi f_{i+1/2} = & \Delta \xi \xi f_{i+1/2} + \Delta \xi f_{i+1/2} \\
\Delta \xi f_{i-1/2} = & \Delta \xi \xi f_{i-1/2} + \Delta \xi f_{i-1/2} \\
\tilde{u}_{i+1/2} = & \tilde{u} + \tilde{\xi}_{i+1/2} \tilde{u} \\
\tilde{u}_{i+1/2} = & \tilde{u} + \tilde{\xi}_{i+1/2} \tilde{u} \\
\tilde{u}_{i+1/2} = & \tilde{u} + \tilde{\xi}_{i+1/2} \tilde{u} \\
\Phi_i = & \phi_i - \phi_{i-1} \\
\Phi_i = & \phi_i - \phi_{i-1} \\
\Phi_i = & \phi_i - \phi_{i-1} \\
\tilde{u} = & \text{sonic value of } \phi_i \\
\tilde{u} = & \text{sonic value of } \phi_i \\
\tilde{u} = & \text{sonic value of } \phi_i \\
\epsilon_{i+1/2} = 1 \text{ if } & \tilde{u}_{i+1/2} > \tilde{u} \\
\epsilon_{i+1/2} = 0 \text{ if } & \tilde{u}_{i+1/2} \leq \tilde{u}
\end{align}
where \( C = E + 2F\alpha \) and \( D = \sqrt{4A + B^2/\alpha} \). These boundary conditions are numerically imposed by redefining the \( L_x \), \( L_\eta \), and \( L_\zeta \) operators in Eq. (7) as well as the right-hand side \( R \), at the appropriate grid points. The equation to be solved at boundary grid points may then be written symbolically as

\[
\tilde{L}_x \tilde{L}_\eta \tilde{L}_\zeta \Delta \phi = -\sigma \tilde{R}
\]

(14)

where the "tilde" indicates that the quantity has been rewritten to account for the boundary conditions. For example, along the downstream boundary the three operators and right-hand side are defined as

\[
\tilde{L}_x = 1 + \frac{4\Delta t}{3} \frac{B}{C} + \frac{D}{\sqrt{C}} \frac{\partial}{\partial \zeta} \tag{15a}
\]

\[
\tilde{L}_\eta = 1 \tag{15b}
\]

\[
\tilde{L}_\zeta = 1 \tag{15c}
\]

\[
\tilde{R} = \frac{1}{3} (3\phi^* - 4\phi^0 + \phi^{* - 1}) + \frac{4\Delta t}{3} \frac{B}{\sqrt{C}} \frac{\partial}{\partial \zeta} \phi^* \tag{15d}
\]

**Time-Linearization Step**

An initial estimate of the potentials at time level \((n+1)\) is required to start the iteration process. This estimate is provided by performing a time linearization calculation. The equations governing the time-linearization step are derived in a similar fashion as the equations for iteration. The only difference is that the equations are formulated by linearizing about time level \((n)\) rather than the iterate level \((^\ast)\).

**CAP-TSD Code**

The AF algorithm has been used as the basis of the CAP-TSD code for transonic unsteady aerodynamic and aeroelastic analysis of realistic aircraft configurations. The code can treat configurations with arbitrary combinations of lifting surfaces and bodies including canard, wing, tail, control surfaces, tip launchers, pylons, fuselage, stores, and nacelles. The present capability has the option of half-span modeling (Eq. (139)) for symmetric cases or full-span modeling (Eq. (131)) to allow the treatment of antisymmetric mode shapes, fuselage yaw, or unsymmetric configurations such as an oblique wing or unsymmetric wing stores. Steady and unsteady CAP-TSD pressures for several realistic aircraft configurations, including comparisons with experimental data, were presented in Ref. 2. The calculated results were in good agreement with the experimental pressure data which validated CAP-TSD for multiple component applications with mutual aerodynamic interference effects. Preliminary aeroelastic applications of CAP-TSD compared well with experimental data for subsonic as well as supersonic freestream Mach numbers which gives confidence in the code for aeroelastic prediction.

**Results and Discussion**

Results are presented for several configurations to demonstrate and evaluate the modifications to the AF algorithm of the CAP-TSD code. Calculations are first presented for a flat plate airfoil to assess the effectiveness of the nonreflecting far field boundary conditions. Calculations are next presented for the F-5 wing and the ONERA M6 wing to demonstrate the improvements due to the Engquist-Osher switch, the second-order accurate supersonic differencing, and the steady-state convergence acceleration. Finally, steady and unsteady results are presented for the General Dynamics one-ninth scale F-16C aircraft model to investigate application of the modified algorithm to a realistic aircraft configuration.

![Comparisons of unsteady lift-curve slope for a flat plate airfoil at M = 0.85.](image)
Flat Plate Airfoil Results

Unsteady results were obtained for a flat plate airfoil at \( M = 0.85 \) to test the nonreflecting far field boundary conditions. The flat plate airfoil was selected to allow direct comparison of results with the exact kernel function method of Bland.\(^{14}\) The boundary conditions were tested by computing the lift coefficient due to the airfoil pitching about the quarter chord. Such unsteady forces are typically determined by calculating several cycles of forced harmonic oscillation with the last cycle providing the estimate of the forces. Alternatively, the forces may be obtained indirectly from the response due to a smoothly varying exponentially shaped pulse.\(^{15}\) In this procedure, the airfoil is given a small prescribed pulse in a given mode of motion (in this case pitching) and the aerodynamic transients calculated. The harmonic response is obtained by a transfer-function analysis using fast Fourier transforms. Use of the pulse transfer-function technique gives considerable detail in the frequency domain with a significant reduction in cost over the alternative method of calculating multiple oscillatory responses. For the flat plate airfoil, pulse transient calculations were performed using 1024 time steps with \( \Delta t = 0.2454 \). The amplitude of the pulse was 0.5. The grid extended 25 chordlengths above and below the airfoil, and 20 chordlengths upstream and downstream of the airfoil. Parallel results were obtained using reflecting (steady-state) and nonreflecting far field boundary conditions as shown in Fig. 1. The results are plotted as real and imaginary components of the unsteady lift-curve slope \( \alpha_0 \) as a function of reduced frequency \( k \). Computations using the reflecting boundary conditions, shown in Fig. 1(a), produce

![Fig. 2](image-url) Effect of step size on the solution computed using the Murman switch for the F-5 wing at \( M = 0.9 \) and \( \alpha_0 = 0^\circ \).

![Fig. 3](image-url) Effect of deleting time derivatives in the residual on the solution computed using the Engquist-Osher switch for the F-5 wing at \( M = 0.9 \) and \( \alpha_0 = 0^\circ \).
oscillations in both the real and imaginary parts for $0 < k < 0.2$. The oscillations are produced by reflected disturbances which propagate back into the near field and contaminate the solution. When the calculation was repeated using the nonreflecting boundary conditions, shown in Fig. 1(b), the oscillations no longer occur since the boundary conditions absorb most of the disturbances that are incident on the grid boundaries. Furthermore, these results are in excellent agreement with calculations from the kernel function method of Ref. 14.

**F-5 Wing Results**

Calculations were next performed for the F-5 wing,\textsuperscript{10} to assess the algorithm modifications to CAP-TSD. The F-5 wing has an aspect ratio of 3.16, a leading edge sweep angle of 31.9°, and a taper ratio of 0.28. The airfoil section of the wing is a modified NACA 65A004.8 airfoil which has a drooped nose and is symmetric aft of 40% chord. The F-5 calculations were performed using a constant step size for a total of 500 steps. The freestream Mach number was selected as 0.9 and the wing was at 0° angle of attack. The results were obtained to study the steady-state convergence characteristics of the modified AF algorithm. The results are presented in the form of convergence histories and the number of supersonic (NSUP) points versus the iteration number.

In the original AF algorithm of Ref. 4, the Murman type-dependent switch was used. Results obtained using the unmodified code are presented in Fig. 2. The steady-state convergence is shown in Fig. 2(a); the number of supersonic

![Graph](image1)

(a) steady-state convergence.

![Graph](image2)

(b) number of supersonic points.

Fig. 2 Effect of deleting all TSD time derivatives on the solution computed using the Engquist-Osher switch for the F-5 wing at $M = 0.9$ and $\alpha_0 = 0^\circ$.
points (NSUP) normalized by the final value are shown in Fig. 2(b). For aeroelastic analysis where airloads are required rather than pressures, the solution is considered to be converged when the order-of-magnitude reduction in the solution error is obtained. The "error" in the convergence history, as defined herein, is the ratio of the maximum $|\Delta e|$ after $n$ iterations to the maximum $|\Delta e|$ in the initial solution (first iteration). Two sets of results are plotted corresponding to two values of step size, $\Delta t = 0.1$ and 0.5. For $\Delta t = 0.1$, the rate of convergence is slow and the number of supersonic points oscillates about the final value. Increasing the step size to $\Delta t = 0.5$ improves the rate of convergence and the oscillations in NSUP are significantly damped. The results for $\Delta t = 0.5$ also indicate that the number of supersonic points is initially more than four and one-half times the final value and that "spikes" begin to appear in the convergence history after 150 steps. These spikes, which represent a numerical instability, are due to a large transient caused by the impulsive start from a uniform stream using a large step size. If the calculations were started with a smaller step size, and then the step size increased to the larger value, the numerical instability can be avoided. As shown in Fig. 3, the step size may be cycled through very large values such as $\Delta t = 5.0$ to achieve faster convergence to steady-state.

The F-5 calculations with $\Delta t = 0.5$ were then repeated with the E-O switch replacing the Murman switch. These results are labeled "unsteady residual" in Fig. 3. The curves are identical (within plotting accuracy) to the $\Delta t = 0.5$ curves of Fig. 2 except that the spikes in the convergence history are absent. The E-O switch is more robust than the Murman switch and thus the calculation remains stable. Furthermore, the rate of convergence to steady-state could be increased by deleting the time derivatives in the residual. These results, which are labeled "steady residual" in Fig. 3, show that after the first 70 steps the solution converges faster and the initial overprediction of NSUP is less than that computed using the unsteady residual.

The convergence to steady-state could be further accelerated by over-relaxing the residual as shown in Fig. 4. The results labeled "original residual" are the same as the "steady residual" curves presented in Fig. 3. The over-relaxed residual results of Fig. 4 were obtained by doubling the residual using $\sigma = 2.0$. These results indicate a faster rate of convergence, especially in the first part of the calculation, and that NSUP is within 2% of its final value after only approximately 50 steps.

To further investigate the convergence characteristics of CAP-TSD, the algorithm was modified to solve the steady TSD equation by deleting all of the time derivatives. Calculations for the F-5 wing were performed using $\Delta t = 0.5$ and $\sigma = 1.0$ to directly compare with parallel results obtained by solving the unsteady TSD equation. These comparisons are presented in Fig. 5. The convergence history computed using the steady algorithm is monotonically decreasing and very smooth in comparison with the unsteady algorithm convergence history. The steady algorithm solution converges faster and does not produce the large initial overprediction of NSUP that is characteristic of the unsteady algorithm. The number of supersonic points converges rapidly to within 2% of its final value in only approximately 25 steps. Over-relaxing the residual of the steady algorithm also further accelerates the convergence to steady-state (not shown).

**ONERA M6 Wing Results**

To test the accuracy of the modified CAP-TSD algorithm, calculations were performed for the ONERA M6 wing. The M6 wing has an aspect ratio of 3.8, a leading edge sweep angle of 30°, and a taper ratio of 0.562. The airfoil section of the wing is the ONERA "D" airfoil which is a 10% maximum thickness-to-chord ratio conventional section. The freestream Mach number was selected as $M = 0.84$ and the wing was at 3.0° of attack. These conditions were chosen for comparison with the tabulated experimental pressure data of Ref. 11. This rather well-known case is a very challenging one, especially for a TSD code, because of the complex double shock wave which occurs on the upper surface of the wing.

Steady-state calculations were performed for the M6 wing by using the AF algorithm with the E-O switch. The results were obtained by cycling the step size through values as large as $\Delta t = 2.0$ for a total of 500 steps. This relatively large step size corresponds to two root chords of travel per time step. A comparison of the resulting CAP-TSD pressures with the experimental pressure data is given in Fig. 6 for two chords along the span. Results for $\tilde{\eta} = 0.44$ are shown in Fig. 6(a); results for $\tilde{\eta} = 0.65$ are shown in Fig. 6(b). The data indicate that there is a relatively weak highly-accurate supersonic-to-supersonic shock wave which forms forward near the leading edge. The primary supersonic-to-subsonic shock which occurs in the midchord region of the wing, coalesces with the first shock. Outboard toward the tip, the two shocks merge to form a single supersonic-to-subsonic shock wave. The CAP-TSD results, obtained using first-order-accurate differencing in supersonic regions, are in fairly good agreement with the data in predicting the overall pressure levels, although differences occur in the regions of the shocks. In general, the leading edge suction peak is well predicted but the supersonic-to-supersonic shock is smeared. When the calculation was repeated using the second-order-accurate spatial differencing, a significant improvement was obtained in the accuracy of the results. The comparisons in Fig. 6 show that the supersonic-to-supersonic shock is much more sharply captured by the second-order method and consequently the calculated pressures are now in very good agreement with the experimental data. Calculations were also performed for the M6 wing using the original algorithm with the Murman switch. These calculations were unsuccessful because of a numerical instability which was produced by the highly expanded flow about the leading edge of the wing.

An unsteady calculation was also performed for the M6 wing at $M = 0.84$, to investigate the robustness of the modified algorithm for time-dependent applications. In this demonstration calculation, the wing was forced to oscillate in pitch about a line perpendicular to the root at the root midchord. The amplitude of the motion was $2^\circ$ peak-to-peak about the mean angle of attack at $\alpha = 3.0^\circ$. The reduced frequency was selected as $k = 0.1$ and only 300 steps per cycle of motion were used. This corresponds to a step size of $\Delta t = 0.1047$. Three cycles of motion were computed to obtain a periodic solution. Unsteady pressure distributions, obtained using first-order and second-order accurate supersonic differencing, are shown at the maximum pitch angle ($\alpha = 4.06^\circ$) in Fig. 7. Results for $\tilde{\eta} = 0.44$ are shown in Fig. 7(a); results for $\tilde{\eta} = 0.65$ are shown in Fig. 7(b). Similar to the steady-state results, these pressure
Comparisons illustrate that the supersonic-to-supersonic shock is more sharply captured by the second-order method. Further instantaneous pressure distributions at two points during the third cycle of motion are shown in Fig. 8 for five span stations along the wing. Pressures at the wing maximum angle of attack \( \alpha = 4.06^\circ \) and pressures at the wing minimum angle of attack \( \alpha = 2.06^\circ \) are both presented in the figure. As the wing pitches up, the shocks move aft and the supersonic-to-subsonic shock grows in strength. As the wing pitches down, the shocks move forward and the supersonic-to-supersonic shock is more sharply defined. For this case, both of the shocks oscillate over approximately 10\% of the chord during a cycle of motion. Also, the supersonic-to-supersonic shock at \( \bar{\eta} = 0.80 \) periodically appears and disappears during a cycle of motion. The results illustrate the large shock motions that the modified AF algorithm is capable of computing. The improved algorithm captures the shocks sharply and is sufficiently robust to compute this complex unsteady flow using only 300 steps per cycle of motion.

**General Dynamics F-16C Aircraft Model Results**

Results were also obtained for the General Dynamics F-16C aircraft model\textsuperscript{12} to investigate application of the modified algorithm to a realistic aircraft configuration. Shown in Fig. 9 are the F-16C components that are modeled using CAP-TSD. The F-16C is modeled using four lifting surfaces and two bodies. The lifting surfaces include: (1) the wing with leading and trailing edge control surfaces, (2) the launcher, (3) a highly-swept strake, aft strake, and shelf surface, and (4) the horizontal tail. The bodies

**Fig. 7** Effects of first-order and second-order accurate supersonic differencing on the unsteady pressure distributions of the ONERA M6 wing during the third cycle of rigid pitching at \( M = 0.84, \alpha_0 = 3.06^\circ, \alpha_1 = 1.0^\circ \), and \( k = 0.1 \).
include: (1) the tip missile, and (2) the fuselage. Other salient features of the F-16C modeling include 30° linear twist washout for the wing, a leading edge control surface hinge line that is straight but not of constant-percent chord, and 10° anhedral for the horizontal tail. In these calculations, the freestream Mach number was $M = 0.9$ and the F-16C aircraft was at a 2.0° angle of attack. Also, the leading edge control surface of the wing was deflected upwards 2° for comparison with the experimental steady pressure data of Ref. 13. Furthermore, the calculations were performed on a grid which conforms to the leading and trailing edges of the lifting surfaces and contains 324,000 points. Since the grid is Cartesian, it was relatively easy to generate, even for such a complex configuration as the F-16C aircraft. Also, the calculations required only about 0.88 CPU seconds per time step and thirteen million words of memory on the CDC VPS-32 computer at NASA Langley Research Center.

Steady-state calculations were performed for the F-16C aircraft using the AF algorithm with the E-0 and Murman switches. The E-0 results were obtained using both the first-order and second-order accurate supersonic differencing. Steady pressure comparisons are given in Fig. 10 for three span stations of the wing and one span station of the tail. Both sets of E-O results are presented for comparison with the experimental data. The results obtained using the Murman switch were originally published in Ref. 2. These results are identical to plotting accuracy with the first-order E-O results, and therefore are not shown. The steady pressure comparisons indicate that there is a moderately strong shock wave on the upper surface of the wing and the CAP-TSD pressures agree well with the experimental pressures. For the tail, the flow is primarily subcritical and the calculated results again agree well with the data. Comparison of pressures computed using first-order and second-order accurate supersonic differencing shows very small differences. The largest difference, for example, occurs on the wing at $\eta_w = 0.79$ where the second-order calculation predicts a slightly stronger shock.

Unsteady results were also obtained for the F-16C aircraft to investigate the robustness of the modified algorithm for realistic-aircraft time-dependent applications. For simplicity, the calculation was performed for a rigid pitching motion where the entire aircraft was forced to oscillate about the model moment reference axis at a reduced frequency of $k = 0.1$. The oscillation amplitude was chosen as $\alpha_1 = 1.5^\circ$ which is three times the value used to obtain similar results presented in Ref. 2. Three cycles of motion were computed using 300 steps per cycle of motion corresponding to $\Delta t = 0.1047$. Calculations were performed using both the Murman and E-O switches. The solution using the original algorithm with the Murman switch, however, was numerically unstable for this case as shown in Fig. 11. Instantaneous pressure distributions at time steps 94 and 95 are plotted in the figure, computed using the Murman (Fig. 11(a)) and E-O (Fig. 11(b)) switches. The numerical instability begins in the region of the launcher/tip-missile where the grid spacing is smallest. Figure 11(a) shows the instability in the form of an oscillation in the wing upper surface pressure distribution at $\eta_w = 0.94$ from approximately 30% to 60% chord. The program subsequently failed during step 96 which is 21 steps after the maximum pitch angle in the first cycle of motion. The

![CAP-TSD modeling of the General Dynamics one-ninth scale F-16C aircraft model.](image)
calculation involving the modified algorithm (E-O switch with the first-order accurate supersonic differencing) is stable, however, as shown in Fig. 11(b). Here the pressure distributions for steps 94 and 95 are very similar and the calculation proceeds with no difficulty. In fact, the modified AF algorithm with the E-O switch is numerically stable for this case with either the first-order or second-order supersonic differencing.

Unsteady pressure distributions along the wing and tail during the third cycle of motion are shown in Fig. 12, computed using the E-O switch with the second-order accurate supersonic differencing. Two sets of calculated pressures are presented corresponding to the aircraft at the maximum ($\alpha = 3.88^\circ$) and minimum ($\alpha = 0.88^\circ$) pitch angles. Comparison of the results indicates that large changes in pressure occur along the upper and lower surfaces of the wing as the aircraft oscillates in pitch. For example, the shock on the wing upper surface oscillates over more than 10% of the chord during a cycle of motion. Also, the shock is approximately twice as strong at the maximum pitch angle as it is at the minimum pitch angle. For the tail, the changes in the pressure distributions due to aircraft pitching are relatively very small in comparison with the changes in wing pressures, as further shown in Fig. 12. The tail is located considerably aft of the pitch axis and thus its motion is plunge dominated which results in much smaller airloads for the low value of $k$ considered.

![Fig. 10 Comparisons between CAP-TSD steady pressure distributions computed using first-order and second-order accurate supersonic differencing with the experimental pressure data for the wing and tail of the F-16C aircraft model at $M = 0.9$ and $\alpha_0 = 2.38^\circ$.](image)

Concluding Remarks

Improvements to a time-accurate approximate factorization (AF) algorithm have been implemented for steady and unsteady transonic analysis of realistic aircraft configurations. These algorithm improvements have been made to the CAP-TSD (Computational Aeroelasticity Program - Transonic Small Disturbance) code developed recently at NASA Langley Research Center. The AF algorithm of the CAP-TSD code solves the unsteady transonic small-disturbance equation. The paper described recent changes to the code which have significantly improved the stability of the AF algorithm and the accuracy of the results. The algorithm modifications include: an Engquist-Osher (E-O) type-dependent switch to treat regions of supersonic flow, extension of the E-O switch for second-order spatial accuracy, nonreflecting far field boundary conditions for unsteady applications, and several modifications to accelerate convergence to steady-state.

Calculations were presented for the F 5 wing and ONERA M6 wing which demonstrated applications of the algorithm improvements. The results revealed the superior stability characteristics and computational efficiency of the E-O switch. Much larger time steps were possible using the E-O switch, even for comparatively difficult cases. For the particularly challenging case of the M6 wing at $M = 0.84$ and $\alpha_0 = 3.06^\circ$, the AF algorithm with the E-O switch was found to be stable for time steps as large as $\Delta t = 2.0$. This relatively large step size corresponds to two root chords of travel per time step. Comparisons of results obtained using first-order and second-order supersonic differencing clearly demonstrated the improved accuracy of the second-order method. Changes to the AF algorithm for convergence acceleration, namely deleting time-derivatives from the original unsteady algorithm and over-relaxing the residual, resulted in faster rates of convergence to steady-state. Converged solutions were obtained in only several hundred time steps for the F-5 and M6 wings. An unsteady calculation for the M6 wing undergoing a rigid pitching oscillation demonstrated the robustness of the modified AF algorithm. In this calculation, the shocks oscillated over approximately 10% of the chord and the flow was computed using only 300 steps per cycle of motion. This rather difficult case could not be computed using the original algorithm.

Calculations were also presented for the General Dynamics one-ninth scale F-16C aircraft model to demonstrate application of the modified CAP-TSD code to a realistic aircraft configuration. The F-16C components that were modeled included: the wing with leading and trailing edge control surfaces; a highly-swept strake, aft strake, and shell surface; the tip launcher and missile; the horizontal tail; and the fuselage. Steady pressure results at $M = 0.9$ and $\alpha_0 = 2.38^\circ$ compared well with the experimental data. Unsteady results were presented for the entire F-16C aircraft undergoing a rigid pitching motion with a three degree peak-to-peak oscillation amplitude. The calculation was a challenging one for the modified algorithm since the flow was computed using only 300 steps per cycle of motion. In this calculation, the shock on the upper surface of the F-16C wing oscillated over more than 10% of the chord which further demonstrates the robustness of the modified algorithm. Also, similar to the M6 wing example, this case could not have been computed using the original algorithm. Therefore, the modifications have significantly improved the numerical stability of the AF algorithm and the general reliability of the CAP-TSD code for realistic aircraft applications.

This paper will be presented at the AIAA 26th Aerospace Sciences Meeting, Reno, Nevada, January 11-14, 1988 as AIAA Paper No. 88-0105.

Improvements to a time-accurate approximate factorization (AF) algorithm have been implemented for steady and unsteady transonic analysis of realistic aircraft configurations. These algorithm improvements have been made to the CAP-TSD (Computational Aeroelasticity Program - Transonic Small Disturbance) code developed recently at NASA Langley Research Center. The code permits the aeroelastic analysis of complete aircraft in the flutter critical transonic speed range. The AF algorithm of the CAP-TSD code solves the unsteady transonic small-disturbance equation. The algorithm improvements include: an Engquist-Osher (E-O) type-dependent switch to more accurately and efficiently treat regions of supersonic flow, extension of the E-O switch for second-order spatial accuracy in these regions, nonreflecting farfield boundary conditions for more accurate unsteady applications, and several modifications which accelerate convergence to steady-state. Calculations are presented for several configurations including the General Dynamics one-ninth scale F-16C aircraft model to evaluate the algorithm modifications. The modifications have significantly improved the stability of the AF algorithm and hence the reliability of the CAP-TSD code in general. The paper presents detailed descriptions of the algorithm improvements along with results and comparisons which demonstrate the improved stability, accuracy, and efficiency of the CAP-TSD code.
