April 1988
ABSTRACT

This is the final report for the shuttle rocket booster computational fluid dynamics. The basic formulations and preliminary results were submitted in November, 1987. Additional results and a revised and improved computer program listing are reported herein. Numerical calculations for the flame zone of solid propellants are carried out using the Galerkin finite elements, with perturbations expanded to the zeroth, first, and second orders. The results indicate that amplification of oscillatory motions does indeed prevail in high frequency regions. For the second order system, the trend is similar to the first order system for low frequencies, but instabilities may appear at frequencies lower than those of the first order system. The most significant effect of the second order system is that the admittance is extremely oscillatory between moderately high frequency ranges.
CHAPTER I

INTRODUCTION

Determination of oscillatory pressure and velocity variations from their mean values in solid propellant combustion chambers has been the subject of study for many years. Because of computational difficulties, however, rigorous and accurate methods of solution still remain in various stages of development. Often details of physics are obscured in complicated computational strategies. In view of the fact that reliable experimental measurements are difficult to obtain, it is crucial to possess an analytical tool to accurately predict combustion dynamics and combustion efficiency in designing successful solid propellant rocket motors.

Earlier works on combustion dynamics include Hart and McClure [1], Denison and Baum [2], Culick [3] and T'ien [4] among others. These studies are centered around one-dimensional, linear oscillatory burning. Culick [5,6], Baum and Levine [7], and Yang et al. [8] subsequently studied the nonlinear growth and limiting amplitude of acoustic waves in a combustion chamber. Nonlinear behavior as characterized by higher order perturbation expansions of governing equations has been investigated by Flandro [9] and Chung and Kim [10] in recent years. They assumed that the pressure varies sinusoidally with time, the pressure
amplitudes being a function of position.

In the present approach, the pressure is assumed to vary in the unstable state. This allows the presence of a long flame such as in double-base solid propellants, in which high pressures and high frequencies may be accommodated. Galerkin finite elements [11] are utilized to model numerically the geometries of burning surfaces and the flame thickness. The nonsteady governing equations are linearized by means of the zeroth, first, and second order perturbation expansions. The boundary conditions, including the burning surfaces and flame edges, are imposed by means of the Lagrange multipliers.

In the simple example problems demonstrated in this paper, the gaseous flame is assumed to follow the Arrhenius law with one-step forward chemical reactions. No condensed phase reaction is included in the formulation. The calculated results confirm the prediction reported by other investigators in the literature for the low frequency region. Extended studies are then carried out for the high frequency region. It has been found that amplification of oscillatory motions does prevail in the high frequency region.

The present study does not include turbulent boundary layers which may play an important role in erosive burning and combustion instability; this is the subject of future study.
CHAPTER II
ANALYSIS AND DISCUSSION OF RESULTS

To demonstrate the validity of the theory presented above, a two-dimensional rectangular geometry, shown in Fig. 1, is analyzed, in which a burning surface and flame edge can be established as boundaries. This configuration was chosen to resemble a one-dimensional behavior so that the results may be compared directly with those reported in the literature [4,9]. The constants and parameters used in this analysis are shown in Table 1.

The computations begin with finding the natural frequencies of the system. The resonance frequencies of the system can be obtained by examining the acoustic admittance or response function at each natural frequency. As mentioned earlier, the natural frequencies of the system are given by the homogeneous solution of the total matrix equation, neglecting the boundary conditions. The frequency range of interest in this computation is shown to be between \( \omega = 10^{-3} \) and \( \omega = 10^{2} \), corresponding to approximately 80 Hz and 8 MHz, respectively. Thus, sixteen different frequencies in this range are chosen to evaluate the present study, and these are \( \omega = 10^{-4}, 5 \times 10^{-4}, 10^{-3}, 5 \times 10^{-3}, 10^{-2}, 5 \times 10^{-2}, 10^{-1}, 5 \times 10^{-1}, 1, 5, 10, 20, 30, 40, 50, \) and 100.

Figure 2 shows a typical steady-state distribution of
the field variables and the reaction rate along the flame thickness. In general, these data may be obtained by solving the energy equation together with the reaction rate. Ideally, a fourth order Runge-Kutta scheme may be used for this purpose. The result will be used as the basis of further calculations for combustion instability in the unsteady-state.

Distributions of the field variables versus frequency for the first order system are shown in Figs. 3-8. These results are obtained by imposing an acoustic pressure amplitude of unity at the flame edge as the Dirichlet condition. Conventionally, the thickness of the burning zone has been assumed to be negligibly small compared with the wavelength of the acoustic oscillation in the intermediate frequency range. Thus, the uniform pressure is approximated throughout the domain of study and is assumed to vary with time only. On the contrary, since the oscillatory pressure is regarded as a spatially nonhomogeneous time-dependent source in the present study, it is possible to investigate the response of a specific solid propellant at significantly high frequencies and to find the response even in the long flame of a double-base propellant. Figure 3 shows variations of the pressure distribution versus the acoustic frequencies. It is seen that the amplitude remains constant for \( \omega < 10 \). Random variations of these amplitudes occur for higher frequencies. Here, the imaginary parts representing the
phase shift are zero.

Figure 4 demonstrates distributions of various component fluctuations of the first order system at \( \omega = 1 \). A pressure wave with a certain amplitude striking the solid surface will give rise to a response in the burning rate. Generally, the response of the burning rate is nonlinear and has a complete Fourier series form that may not be expressed by a single frequency component. In Fig. 4, however, the pressure is uniform in the flame zone, although significant variations may occur at higher frequencies.

The temperature amplification at the surface changes the burning rate, while the velocity at the flame edge represents the acoustic admittance for pressure coupling, whose magnitude and sign indicate the instability of the system. Since the pressure remains constant, implying that the acoustic wavelength is larger than the flame thickness in this case, the imaginary part of the velocity approaches a constant slope at the edge by the assumption of an isentropic condition at the flame edge. It is interesting to note that the trend of variations of temperature and velocity appears to be similar, which is inversely proportional to the variations of species and density as expected. These results are comparable to those of T’ien [4] and Flandro [9].

Density distributions for various frequencies are given in Fig. 5. At \( \omega < 0.5 \), changes of the distributions
versus frequency are negligible; however, near \( \omega = 1 \) a significant reduction of the amplitude occurs, and then for \( \omega > 1 \) the amplitudes increase moderately. The distributions in the lower frequency region are very similar to those in the steady-state, from which the quasi-steady assumption may be deduced. Note that the reverse peak moves in the flame zone, which implies a change of the reaction zone. Close to the surface, the effect of preheat in the solid phase increases, resulting in a higher burning rate. Positive amplitudes at the interface in each frequency are caused by the rise in pressure and/or the increase of the burning rate.

It is interesting to see that the amplitudes decrease while the frequency increases up to the unity and then increase along the frequency, from which the flame is expected to react sensitively at special frequencies. The negative amplitude is shown most notably at \( \omega = 1 \). This may result from the net blowing effect, and the velocity at that point should be positive (see Fig. 8).

The normal velocity distributions are shown in Fig. 8. The profile may be classified into positive and negative slopes, the only exception being at \( \omega = 1 \). The latter contains most of the distributions in the lower frequency region. Negative amplitudes appear mostly at the interface, relating to an increase of the density. Although the pressure remains constant in lower frequencies, the velocity varies severely. At \( \omega > 20 \), the
variation is more significant since from that frequency the pressure varies in the flame zone. At $\omega = 0.01$, note that the slope is positive even though it is a lower frequency. This result implies instability of the system for the quasi-steady case. At $\omega = 1$, a positive amplitude near the interface results from adjusting between the density increase and the higher gasification rate. As indicated in Fig. 4, the slopes of the imaginary parts near the flame edge are constant.

Rearranging the real part of the velocity at the flame edge gives the distribution of the acoustic admittance, whose magnitude and sign indicate the amplifications or damping ability of the flame subject to the acoustic disturbance. Figure 9 shows the curve-smoothed acoustic admittance and burning rate at each frequency.

At $\omega = 1$, there is a definite increase in the burning rate. The burning rate increases by increasing the heat transfer effect due to closer movement of the reaction zone to the surface. There are actually several secondary effects such as structural change in the solid phase and change of the chemical kinetics in the flame. These effects cause the feedback to the solid phase, resulting in a change of the burning rate. These effects, however, are not considered.

Figure 9 also reveals a resonance in the condensed phase near $\omega = 0.01$, indicating that the system is unstable. This verifies the result of Denison and Baum [2]
and previous laboratory measurements which have shown that the response consists generally of a single peak in the range of frequency for which the quasi-steady approximation appears to be accurate. Some negative peaks exist at the other frequencies, implying that the resonance in the gas phase tends to damp the oscillatory motion. At most higher frequencies, the system seems to be unstable.

The real part of the burning rate shows a trend similar to the acoustic admittance at the quasi-steady region, although the magnitude is significantly different. But these trends differ from each other at the higher region. Over $\omega = 100$, the profile tends to have a second mode oscillation as the pressure varies in the flame zone. It must be emphasized that the admittance function alone is not sufficient to describe the stability of the system unless the velocity coupling is concerned.

Temperature distributions are given in Fig. 6. Since the temperature is related to the density, it can be analyzed easily by comparing the results with those in Fig. 5. Accordingly, the distribution of the temperature shows the profile opposed to that of the density. Temperature rises are predominant along the reaction region for $\omega > 1$. Note that no significant temperature changes occur at the interface as imposed by the boundary conditions. Negative amplitude near the flame edge may be caused by the stagnation phenomena in which the density increases. Because of the pressure unity, the imaginary parts of the
temperature are given as reciprocals of those of the density.

The fuel consumption at a given frequency is shown in Fig. 7. Trends for species distributions are opposite to those for temperature distributions in that negative maximum occurs along the reaction region. Note that linearly diminishing the fuel near the flame edge affects the temperature changes slowly (Fig. 6).

The results of the second order perturbation are shown in Figs. 10-28. As previously indicated, each variable of the second order response to acoustic disturbance has two components: one time-dependent component that oscillates at twice the fundamental frequency and one that is time-independent. The latter represents a shift in the mean value, thus causing a shift of the mean burning rate. It should be noted that the variations for the second order system may be characterized by the sum of those two parts, with the factor $e^{i2\omega t}$ ranging between -1 and 1 and zero indicating the case of time-independence.

Figures 10-15 show the distributions in the second order time-independent case. The calculations are also conducted by imposing the pressure of unity at the flame edge as the Dirichlet condition. General trends show that shifts in the mean values are evident.

In Fig. 10, the pressure varies from $\omega = 5$, which is half of that in the first order system. For the higher frequency region, the oscillatory motion is significant,
which may affect the velocity distribution. Figure 11 shows all of the variables for $\omega = 1$, indicating that shifts in mean values may have the affect of damping; however, the opposite may be true for higher frequencies as demonstrated in Figs. 12-15. The trends are roughly similar to those of the first order illustrated in Fig. 4a, but they have different amplitudes because of the nonlinearities in the higher order system. In Figs. 12-15, the distributions of field variables in lower frequencies appear to vary negligibly along the flame thickness, while the opposite is true for $\omega > 1$. In particular, since the pressure varies at $\omega > 5$, the velocity changes significantly at those frequencies, implying that the system is unstable at higher frequencies. As mentioned earlier, a shift of the mean burning rate is the most significant effect in the time-independent system. This result will be discussed in Fig. 28.

The distributions in the second order time-dependent case are shown in Figs. 16-21. Here, the pressure also varies from $\omega = 5$ and oscillates for higher frequencies. Note that the amplitude variations are smaller than those in the time-independent case. The trends seem to reduce the total effect of the second order system.

Figures 22-27 show the variations of field variables in the second order system by summing time-independent and time-dependent effects, with the factor $e^{i\omega t} = 1$ for time-dependent effects. Note that amplitude variations of each
variable in the flame zone are significant at \( \omega = 1 \), which is the same result obtained for the case of the first order system. Finally, Fig. 28 reveals that the shift in burning rate versus frequency is consistently negative, as asserted by other investigators. The offset is relatively small in the quasi-steady region, but increases with oscillatory motion along the frequencies. The variations of the acoustic admittance are similar to those of the first order system, except that oscillatory deviations are more predominant at higher frequencies in both time-independent and time-dependent cases.

Parameter studies are conducted for the first order and are summarized as follows. Decreasing the density ratio \( \beta \) affects the variables shifted slightly to the negative direction, keeping the distribution profiles constant. Changing the latent heat of solid \( L \) exerts a negligible effect on the variables, but a very small value of \( L \) shifts the system toward instability. Increasing the surface activation energy \( E_s \) or the gas phase activation energy \( E \) reduces the magnitude of the variables, keeping the same profiles. Changes of the rate constant and viscosity effect coefficient strongly affect the system, such that every aspect discussed herein will change.

The present study could be extended to the multi-dimensional case by introducing the appropriate axial mean flow field. It is well recognized that fluctuation of the gas velocity parallel to the propellant surface affects the
burning rate in terms of velocity coupling; therefore, this quantity must be considered together with pressure coupling for a satisfactory measure of stability.

A simple calculation has been accomplished using the artificial axial flow velocity. However, difficulties of the boundary conditions could not be eliminated. A test run shows that the existence of a small amount of the axial flow reduces differences between the variable amplitudes in each frequency considered, thus leading the system toward stability.
CHAPTER III
CONCLUSION

A multi-dimensional numerical model for the premixed flame acoustic instability is proposed and solved using the finite element method. The governing equations are perturbed to the second order and formulated with the Galerkin finite elements. The results have direct bearing on the validity of published theories of solid propellant combustion instability at the lower frequency region where the uniform pressure assumption is valid. Extended studies are made on the higher frequency region and some new results are obtained.

Under the restricted boundary conditions, the following conclusions, based on numerical computations, are reached:

(1) The stability characteristics for the low frequency range in the first order system have been verified to be the same as those reported in the literature. For example, the acoustic admittance is controlled by the burning rate, negative for low frequencies, whereas the opposite is true for high frequencies.

(2) Instabilities are likely to occur at high frequencies \( (\omega > 10) \).

(3) For the second order system, the trend is similar to the first order system for low frequencies, but
instabilities may appear at frequencies lower than those of the first order system.

(4) The most significant effect of the second order system is that the admittance is extremely oscillatory between $\omega = 1$ and $\omega = 10$.
