SUMMARY

Several incompressible Navier-Stokes solution methods for obtaining steady and unsteady solutions are discussed. Special attention is given to internal flows which involve distinctively different features from external flows. The characteristics of the flow solvers employing the method of pseudocompressibility and a fractional step method are briefly described. The present discussion is limited to a primitive variable formulation in generalized curvilinear coordinates. Computed results include simple test cases and internal flow in the Space Shuttle main engine hot-gas manifold.

INTRODUCTION

Incompressible internal flows are encountered in many realistic engineering problems such as the flow through impeller passages and duct flow. Geometric variation for these flows is diverse and naturally the computational approach has to take this into account. Internal flows are in general very different from the external flows. For instance, the boundary layer in external flow is usually very thin compared to the characteristic length of the moving object, while in internal flow the entire flow field is likely to be viscous. The boundary layer is often separated by abrupt changes in geometry and the blockage effect caused by the separated zone becomes significant.

One of the major motivations of the present work was to develop numerical simulation capability especially suitable for internal flows in the Space Shuttle main engine (SSME) power head. To upgrade the SSME without increasing the weight and size of the existing engine, it became essential to understand the dynamics of the hot-gas flow in the engine power head. Because of the complexity of the geometry, an experimental approach was extremely difficult as well as time consuming. Computational simulation, therefore, offers an economical alternative to complement the experimental work in analyzing the current configuration, and to suggest new, improved design possibilities. The Reynolds number of the primary flow in the power head is of order $10^6$. Because of the high gas temperature, the Mach number is less than 0.12. The flow is turbulent and is practically incompressible. In the past, numerous numerical methods of simulating viscous incompressible flows have been developed (ref. 1). The present paper is a short
summary of our recent effort to develop alternative methods for simulating three-dimensional viscous incompressible flows in generalized coordinates.

This work is partially sponsored by the NASA Marshall Space Flight Center.

**SOLUTION METHODS**

A major problem of solving the incompressible Navier-Stokes equations comes from the lack of a pressure term in the continuity equation. In realistic three-dimensional applications, satisfying continuity in a reasonable amount of computing time becomes a primary issue in addition to accuracy and robustness. For convenience and flexibility, a primitive variable formulation in generalized curvilinear coordinates is chosen, and our discussion is limited to this formulation. In this section, three computer codes recently developed at NASA Ames Research Center and related solution methods used in the codes are summarized. Derivation of equations and algorithmic details can be found in full-length versions of the authors' publications (refs. 2-6).

**Pseudocompressibility Method**

Recent advances in the state of the art in computational fluid dynamics (CFD) have been made in conjunction with compressible flow computations. Therefore, it is of significant interest to be able to use some of these compressible flow algorithms. To do this, the artificial compressibility method (ref. 7) can be used. In this formulation, the continuity equation is modified by adding a time-derivative of the pressure term resulting in a hyperbolic-parabolic type of time-dependent system of equations. This method was originally intended for the steady-state computation of incompressible flows. However, by introducing a pseudotime iteration, this can be made time accurate (refs. 6 and 8).

In an incompressible flow, a disturbance in the pressure causes waves which travel with infinite speed. When pseudocompressibility is introduced, waves of finite speed result in which the magnitude of the speed depends upon the magnitude of the pseudocompressibility. In a true incompressible flow, the pressure field is affected instantaneously by a disturbance in the flow, but with pseudocompressibility, there will be a time lag between the disturbance and its effect on the pressure field (ref. 3). The interaction of the pressure wave propagation and the viscous field is especially pronounced in internal flows (ref. 3). Various applications evolved from this concept have been reported for obtaining steady-state solutions (refs. 2-4, 9 and 10).

**INS3D Code**— By constructing a pseudocompressible form of governing equations, fast, implicit schemes developed for compressible flows, such as the approximate-factorization scheme (ref. 11) can be implemented. The present code is written for obtaining steady-state solutions. The spatial discretization uses second-order central differencing with additional numerical dissipation terms. This code has been validated and numerous three-dimensional problems have been solved using this code (refs. 2-4, 12 and 13).
INSUP Code—To obtain time-accurate solutions using the pseudocompressibility formulation, it is necessary to satisfy continuity at each time step by subiteration in pseudotime. To use a large time step in the pseudotime iteration, an upwind differencing scheme based on flux-difference splitting is used combined with an implicit line relaxation scheme. This removes the factorization error and the need for numerical dissipation terms. The code has been validated and excellent results have been obtained (ref. 6).

Fractional-Step Method

The fractional-step method can be used for time-dependent computations of the incompressible Navier-Stokes equations (refs. 5 and 14-16). Here, the discretized equations are advanced in time by decoupling the solution of the momentum equation from that of the continuity equation. The common application of this method is done by two steps. The first step is to solve for an auxiliary velocity field using the momentum equation in which the pressure-gradient term can be computed from the pressure in the previous time step (ref. 15), or can be excluded entirely (ref. 16). In the second step, the pressure which maps the auxiliary velocity onto a divergence-free velocity field is computed. Various other operator splittings can be adopted by treating the momentum equation as a combination of convection, pressure, and viscous terms.

INSFS Code—A generalized flow solver based on this approach using a staggered grid has been developed (ref. 5). The governing equations are discretized conservatively using finite volumes. Rather than choosing the Cartesian velocity components as dependent variables, the volume fluxes over the faces of the computational cells are used. They are equivalent to the contravariant velocity components described in a staggered grid. This procedure, combined with accurate and consistent approximations of the geometric quantities, satisfies the discretized mass conservation equation exactly. A novel four-color ZEBRA scheme is devised for solving the Poisson equation for pressure correction. Several computational results have been compared with experiments and other numerical solutions in reference 5.

COMPUTED RESULTS

Validation of Flow Solvers

The three flow solvers described above have been validated by computing various basic fluid dynamics problems. A few examples are listed in this section.

In figure 1, vortex shedding from a circular cylinder is summarized by a plot of Strouhal number as a function of the Reynolds number based on diameter of the cylinder. Strouhal number is the dimensionless frequency of the vortex shedding and a good agreement is seen between the computed results obtained by INSUP and the experiments by Kovasznay (ref. 17) and Roshko (ref. 18).

In figure 2, the time evolution of separation length for flow over a circular cylinder at Reynolds number of 40 is compared with one other computation (ref. 19) and with some experimental results (ref. 20). The computed results in figure 2 are obtained using INSFS.
SSME Flow Analysis

In the SSME staged combustion cycle, the fuel is partially burned at very high pressure and relatively high temperature in the preburners. The resulting hot gas is used to run the turbine and is then discharged from the gas turbine to the annular turnaround duct (TAD), and experiences a 180° turn before it diffuses into the fuel bowl. This assembly is called the hot-gas manifold (HGM). The SSME flow simulation was performed using INS3D code.

To simulate this flow undergoing a 180° U-turn, it is necessary to incorporate strong curvature effect in the turbulence modeling. Several levels of turbulence models have been implemented in INS3D code. However, for the present problem, a length scale determined by the point of minimum vorticity is used. This length scale is incorporated into an extended Prandtl-Karmann mixing-length theory. The combination of these automatically account for curvature effect. Full details of this model are given in references 13 and 21. In figure 3(a), the grid in the 180° turn region is shown. In figure 3(b), computed pressure coefficients for the inner and the outer walls are compared with experiment (ref. 22).

In figure 4, the computer model of the current three-duct SSME power head is shown. This model is chosen to analyze critical areas where the dynamics of the hot-gas flow is expected to have a significant effect on the overall performance of the SSME. Multiple zone computations were performed using the grid shown. From this computational flow analysis and also from experiments, the center duct of the current three-duct HGM is found to transfer a limited amount of mass flow (about 10% of the total flow). Also the transverse pressure gradient remains large together with a large bubble of separation after the 180° turn. To reduce this large separation bubble, a parametric study is performed to find the best possible configuration. To improve the quality of the flow, a large-area, two-duct design concept has been developed. In addition, the ducts are chosen to have an elliptical shape to distribute the mass flow evenly to the main injector region. A grid for a two-duct model is shown in figure 5. Computational simulation of this new two-duct configuration shows that the separation bubble existing in the present design is practically removed in the new configuration. This is confirmed by experiments.

The most significant aspect of the present study is to pinpoint the locations where flow experiences the most energy loss. An important measure of the energy losses is the mass-weighted average total pressure along the flow. Figure 6 illustrates the decreasing coefficient of the mass-weighted total pressure along the centerline of the TAD, the fuel bowl, and the transfer duct. The discontinuities shown in the figure correspond to the entrance of the duct where energy fluxes are computed over different planes. In the figure, three different HGM configurations are compared. The initial two-duct design shows 28% less total pressure drop compared to the current three-duct version. After fine-tuning the two-duct configuration computationally, the pressure drop decreased even further to 36% less than the original configuration. This final configuration is then tested using cold air flow, which shows 40% reduction in pressure loss. Further details of this work can be found in references 12, 13, and 23.
CONCLUDING REMARKS

This paper presents a summary of incompressible Navier-Stokes flow-solver development work. Computed results on several validation problems are compared with experiments and other computations. Computational results of the SSME power head are favorably compared with test data, and offer information not readily available from experiments. The results show that CFD can reduce the development time and cost by suggesting the best possible configurations for final verification by experiments. The SSME application provides an example of how the present CFD capabilities can be integrated into the aerospace design process. Further study of the SSME is in progress, and the total performance improvement will be compared in the future.
