April 1988
ABSTRACT

An example of a minimal complexity simulation helicopter math model is presented. Motivating factors are the computational delays, cost, and inflexibility of the very sophisticated math models now in common use. A helicopter model form is given which addresses each of these factors and provides better engineering understanding of the specific handling qualities features which are apparent to the simulator pilot. The technical approach begins with specification of features which are to be modeled followed by a build-up of individual vehicle components and definition of equations. Model matching and estimation procedures are given which enable the modeling of specific helicopters from basic data sources such as flight manuals. Checkout procedures are given which provide for total model validation. A number of possible model extensions and refinements are discussed. Math model computer programs are defined and listed.
FOREWORD

This report was prepared by Manudyne Systems, Inc., for the U. S. Army Aeroflightdynamics Laboratory located at Ames Research Center. The Contract Technical Monitors were Ms. Michelle M. Eshow and Mr. Christopher L. Blanken.

The Manudyne project engineer was Mr. Robert K. Heffley and the math model development effort was conducted by Mr. Marc A. Mnich.

MINIMUM-COMPLEXITY HELICOPTER SIMULATION MATH MODEL PROGRAM

I. Introduction
A. Background

The past decade has seen a trend toward increasingly complex simulator math models. Part of this has been a result of more flight control system sophistication and attention toward a number of aerodynamic factors, including interactive aerodynamics and aeroelastic effects. Another reason is the availability of large, high speed mainframe and mini-computers. Some simulation uses such as aircraft design or failure analysis do justify attention to detail. Other applications, including may handling qualities evaluations, may be better served with lesser sophistication. Since high complexity also carries the burden of high cost of engineering labor and computer facilities, one should exercise judgment in math model design. Engineering management should be concerned when there is a neglect to determine precisely the degree of complexity really needed for a given application.

The purpose of this report is first to discuss the reasons for striving for minimal math model complexity and second to offer an example of a reasonably useful and credible helicopter math model form offering real economy in terms of development and computational requirements. Evaluation of handling qualities is the main application under consideration here, but the same kinds of factors would apply to other simulation uses.

The question being considered is really one of math model value versus cost. The value must ultimately be expressed as the utility of a math model to provide necessary features which can be perceived and used by the simulator pilot. One should expect that, as a function of complexity, this model utility approaches a fairly flat asymptote with some reasonable level of complexity. The other side of the coin is the cost of math model development and checkout, also a function of complexity. Unfortunately this function can be expected to increase exponentially. These contrasting relationships are sketched in Figure 1. The obvious question for the simulator user is at what level of model complexity do these two cost/value curves cross. That is, what is the point of diminishing returns on model complexity?
Experience typical of that described in References 1 and 2 has taught that math model complexity alone does not automatically provide effectiveness in handling qualities simulations. Rather, there can be distracting factors which work counter to simulation objectives. Ultimately, limited resources prevent one from realizing the full potential of an overly complex simulator math model. Other limitations can be a lack of flexibility in modeling and restricted clarity in the cause and effect relationships between model parameters and features. These shortcomings raise questions about the value of complexity in helicopter math models and are a motivation to consider simpler models.

The following are some of the undesirable effects of excessive math model complexity.

1. Computational Delays

Computational lag and delay is a particularly important problem resulting from model complexity. As complexity grows, computational delay associated with the math model code increases and, in turn, compounds overall visual system delay. Computer speed is limited by the hardware and software system being used and cannot be easily changed.
The result of the delays imposed is reduced fidelity. NASA Ames, for example, employs both a Xerox Sigma 8 and CDC 7600 for their Vertical Motion Simulator (VMS). Using the currently implemented ARMCOP helicopter math model (Reference 3) and the faster of the two computers (CDC 7600), the computational delay is about 25 milliseconds. The Sigma may require 60 to 75 milliseconds to cycle. The former speed is acceptable for some math model solutions but visual system digital delay of about 100 milliseconds can still remain. Although the impact of this amount of delay has been minimized at Ames (using methods such as those presented in Reference 4), more software complexity has been added to correct a problem originally caused by complexity. It would seem that this is not as cheap and effective as preventing the problem by simplifying the model in the first place.

2. Cost of Resources

As model complexity and the amount of computer code grows, so do the time and effort required to implement, check, and debug the code. The time available to do these is often limited and can affect overall math model fidelity if neglected. ARMCOP, for example, has several thousand lines of code. In checking and debugging code in large programs, a certain number of errors will go undetected, and the more code there is, the more likely errors will persist.

In addition to checking and debugging code, there is the task of determining model parameters needed to represent a specific aircraft. The time and effort required to thoroughly validate the model against the real aircraft can be an expensive part of any simulation. Math models employing look-up tables can have hundreds of parameters which need to be set and confirmed. Since some of these values are estimates, an iterative process may be required. Limits on time and manpower may restrict this process and the fidelity of the model.

Validation of the math model equations (as opposed to math model code) is also a process which may require iteration as the model is changed. It is possible that errors in the math model will exist even as the model is being used in simulation. Again, the number of errors which exist and the time required to fix them is a function of the complexity of the model. Time and manpower restrictions will limit the ability of the users to find and correct these errors and thus degrade the fidelity of the model. In order to guarantee that a model is completely correct, all parts of the model must be exercised. Lookup tables, for example, require that all numbers in the table be verified as well as checked for discontinuities. All equations in the model need to be checked to ensure they are theoretically sound. With complex code, it is unlikely that all of the model will be checked as thoroughly as necessary and errors can persist in actively used models for long periods of time before they are ever noticed or corrected.
ARMCOF, for example, still exhibits a problem affecting maneuvering flight even though the model has seen wide use. This involves a large speed loss during sustained turns. Although detected, this problem has not been corrected because of insufficient engineering labor resources. Rather problems are "patched up" with flight control system modifications (in this case a turn-coordinator). Again, complexity is added to fix a problem itself arising from model complexity.

3. Inflexibility

There is an inherent tradeoff between complexity and flexibility in models of dynamic systems. As more components or features are added to a model, it becomes increasingly difficult and expensive to perform other modifications. One measure of the flexibility of a model is its adaptability to new computer systems and languages or to changes in the code. Large sets of code are limited to large computer systems. ARMCOF, for example, requires the use of a mainframe system. In order to work with the model, one must have access to such facilities.

Once code has been implemented on a machine, it must be checked and debugged. Modifications for debugging may require recompilation. Most such changes are made before the code is used for actual simulation, but it is possible that they will be made during a simulation. Even simple model changes can consume enough time to hamper simulator productivity. It is not uncommon for a software modification, followed by a graphical check, to require 20 or 30 minutes of simulator occupancy time.

The ability to add, remove, or modify efficiently the dynamic characteristics of a model is another measure of its flexibility. It may be desirable, for example, to have a helicopter simulation without rotor cross coupling. A model such as ARMCOF, in which cross coupling is inherent, does not allow easy removal of this feature. In fact, coupling might be "removed" by adding control system functions to suppress the coupling, thus further increasing the complexity of the model. The emphasis in modeling should be on efficiency while maintaining adequate fidelity.

4. Indirectness of Cause and Effect Relationships

The ability to see the relationship between model parameters and model response features is decreased with complexity. This relationship is important to handling qualities simulation work for two reasons. First, is the need to easily make changes in model features. Second is the need to trace errors which appear in the response modes of the model. These are fundamental to working effectively with the model. In order to modify response features, one must know what parameters are responsible for those features and how to change them. In any math model, individual parameters tend to become coupled to many
features at once making it difficult to change such features independently. The more complicated that math model, the more impossible is it to manage individual model response features.

B. Merits of Considering a Simple Math Model Form

Turning from the above list of difficulties issuing from model complexity, consider some of the direct, positive aspects of considering a simple math model form at the outset.

It would appear that there are compelling benefits for general reductions in the levels of complexity exemplified by math models such as ARMCOP and GENHEL (Reference 5). This leads us to consider ways to find a compromise between math model complexity and simulator utility. At one extreme are the highly complex models which attempt to achieve effectiveness through high computational fidelity. As mentioned, these models encounter practical limits which not only hamper fidelity but also reduce their flexibility and clarity between parameters and features. At the other extreme are models such as the linearized stability derivative form which are easier to manage but which may lack fidelity or be restricted to a small operating envelope.

The merits of a "compromise" model form would thus be cost and quality benefits derived from the achievement of specific fidelity features through minimal software program instructions.

1. Cost

The cost benefits will accrue through minimizing labor required to quantify and checkout the math model implementation. Development of even modest math models typically involve more than one man year of labor. If this process can be shortened to less than one man-month, the period envisioned for the proposed form, then great savings clearly can be realized.

Simulator math model software checkout can also require substantial effort. However, this is often simply limited by time available and the job might not actually be completed prior to simulator use. Again the aim is to realize greatly reduced checkout time through software reduction and to make a comprehensive checkout feasible within a short period of time.

2. Quality

The quality benefits come from confidence that specific features needed for effective simulation are represented and that they are correct. Here quality arises from the fact that implementation and checkout tasks which should be done are, in fact, done. In a real sense, quality follows the degree of manageability afforded by the simulator software.

3. Engineering Understanding
One of the most important benefits to be derived from a minimum-complexity math model is in the potential for more clearly understanding cause and effect relationships. For example, if a particular kind and amount of cross-coupling is desired, then how does one achieve it through adjustment of math model parameters? It is possible by having a close, easy-to-follow connection between the physical component representation and the resulting physical response features.

An important value of engineering understanding is the ability to make model adjustments or refinements in a direct, efficient manner as is possible for a physical helicopter model.

C. Model Attributes to be Considered

1. Simulator Application

It should be stressed that in this case the goal of the math model is to be an effective tool for simulation. Model fidelity alone is not the solution to simulator effectiveness. Rather, it is the ability of the model to produce the desired results and insights for the given application. Besides having adequate fidelity, the model must also be affordable, manageable, easily modified and checked, and have a reasonably clear cause and effect relationship between parameters and response features (at least those perceivable by the pilot).

2. Handling Qualities Application

Thus we are motivated to turn to a simple model with these qualities for helicopter handling qualities simulation which can be a more effective tool than existing models. Specifically, the purpose here is to propose a minimum-complexity model format suitable for helicopter handling qualities simulation.

It should be remembered that many handling qualities investigations involve examination of fairly crude and simple parameters such as time constants, damping ratios, or static gains. Furthermore the precision with which evaluation pilots can perceive such changes often can be disappointing to the engineer. Thus it is not reasonable to expect that high math model resolution is really crucial. If a pilot cannot actually observe or be influenced by certain math model effects then those effects should probably be considered as excessive complication. (Unfortunately, there is presently little quantification of just how sensitive a pilot is to various effects, and this is a potential application of a minimum-complexity math model.)

3. Full Flight Envelope Operation

The model should be nonlinear and apply to the full operating range of a real helicopter including rearward as well as forward flight, sideward flight, hover, and transition from hover to forward flight. The model should include at least
first-order flapping degrees of freedom and all rigid body degrees of freedom. The higher-order flapping modes and any structural modes beyond the frequency range of interest for handling qualities should not be included unless high-gain flight control systems are involved.

4. Modularity

The form of the model will be modular. This will allow the flexibility of adding alternative rotor models, if desired, as well as other lifting surfaces. Any combination of components can be combined including models of pilots and control systems making the model adaptable to a variety of helicopters and subsystems. The full utility of the proposed model format will become apparent as the structure of the model is described in more detail.

5. Microcomputer Adaptability

The math model form will be compatible with microcomputer use, at least on a non-real-time basis. It has been found that math model development and checkout can be done to a large extent on small, inexpensive desktop microcomputers. This of course demands that the software be reasonably compact.

D. Report Organization

The presentation which follows consists of four parts: (i) approach to modeling, (ii) matching and estimation procedures, (iii) checkout procedures, and (iv) extensions and modifications of the model. In addition various detailed information is contained in appendices.

1. Modeling Approach

In the first section, the modeling approach is described in order to establish the theoretical foundation for the model. This is useful for understanding, modifying or extending the model and for its effective use as a simulator tool. In addition a description of the features and components of this specific model is given. The model is used to represent a Bell AH-1S Cobra. All parameters and variables from this aircraft are provided here along with the actual code. The sample version shows the extent of the code in terms of number of parameters, number of lines of code, number of computations, etc. and can be compared to an ARMCOP version of the same aircraft.

2. Matching and Estimating Procedures

In the next section, the matching and estimating procedures used to obtain model parameters are described. The sample version of the AH-1S is used as a specific example. The model is then exercised and the estimated parameters varied in order to tune the model to fit performance data.
3. Checkout Procedures

The third section describes several methods of checking the math model code. The size of the model and the modular format are conducive to efficient checking. Methods are then presented for verifying the math model equations and are illustrated using the sample version.

4. Model Extensions and Refinements

Finally, in the last section, possibilities for extending or modifying the model are introduced to demonstrate the flexibility of the model format. The potential for a much improved level of simulation effectiveness using these extensions and modifications is revealed and explained in terms of the approach taken to the modeling process.
II. Technical Approach

A. Specification of Desired Math Model Features

The approach to modeling will begin with a list of desired features. This list will serve as a specification upon which to formulate a minimum-complexity model containing only those components and equations directly responsible for the desired features. The model will be customized to the problem being studied.

We shall assume that the model is intended for handling qualities simulation and that the features to be included in the model should be features which are observable or needed by a pilot. It should be assumed that the model will be operated over a specified flight envelope and controlled by a given flight control configuration. This sets limits on speed, acceleration, and frequency response. The features to be included by the following example are listed in Table 1. Of course these are subject to change depending upon the application.

1. First-Order Flapping

It has been shown in Reference 6 that rotor flapping can couple with rigid-body modes in regions which affect handling qualities. This occurs in the lower frequency or "regressing flapping" modes. However, this effect can be modeled with a first-order flapping equation in the pitch and roll axes.

The time constant involved in the regressing flapping mode is directly proportional to the product of rotor angular velocity and Lock number. Thus only the commonly available rotor mass and geometric parameters are needed.

The actual flapping response is modified by coupling with the fuselage at the hub restraint. Since this involves the classical rigid body modal response, it is discussed further under items 6 and 7 below.

The feature of flapping which is most important to a pilot-in-the-loop simulation is the apparent control lag following cyclic input. This lag is in effect the time required to precess the tip path plane to a new orientation. A typical value for the effective lag is about 0.1 sec—significant because it is comparable to the pilot's own neuromuscular lag.

2. Main Rotor Induced-Velocity Computation

A particularly important feature of a helicopter is the relationship among thrust, power, and airspeed. This relationship arises from the induced-velocity of air passing through the rotor disc.

There are a number of complicating factors, but, to a first-order approximation, induced-velocity effects can be modeled with a classical momentum theory model wherein thrust and induced-velocity interact in an aerodynamic feedback loop. Computation is complicated, however, because this feedback is highly nonlinear.

Another aspect of the induced-velocity is its effect on adjacent surfaces. The rotor induced-velocity field impinges on the wing, horizontal tail, and fuselage and varies with airspeed and flight path direction.

3. Rigid-Body Degrees of Freedom

Normally, six rigid-body degrees of freedom are needed for useful manned simulation. Pilot workload arises from constant attention to roll, pitch, and yaw as well as translation fore-and-aft, to the side, and vertically. Only under special conditions might one desire to eliminate one of these via, for example, the assumption of perfectly coordinated forward flight.
4. Power Requirements Over Flight Envelope

A common source of real aircraft data appropriate for verifying a math model is performance data in terms of power required for various trim conditions. The power or torque required is immediately obvious and important to a pilot and varies substantially from hover through transition and finally in forward flight.

Power requirements can be easily computed once main and tail rotor induced velocities are established.

5. Rearward and Sideward Flight

In a full-flight-envelope model involving circulation lifting surfaces, computational singularities can exist, depending upon the model form used. These singularities come from trigonometric functions for angle of attack, sideslip, etc., but are avoided in this model by using a quadratic lift coefficient method. For this technique, forces for lifting surfaces are computed using quadratic coefficients multiplied by the squares of velocity components so that negative velocities cannot cause singularities. No explicit computation of angle of attack or sideslip is needed and, indeed, should be completely avoided.

6. Hover Dynamic Modes

Hovering flight is characterized by similar dynamics in each the pitch and roll axes, including sets of high and low frequency response modes. In addition, the yaw axis contains a predominant yaw damping mode. These dynamics can couple with regressing flapping dynamics. All are apparent to the pilot in operating the aircraft whether trimming, maneuvering, or flying unattended.

Pitch and roll are classically described by the "hover cubic," but this generally neglects coupling with the rotor which can be important. This is easily computed, however, through inclusion of the flapping dynamics as described earlier.

The phugoid mode for hover results from the combination of dihedral and gravity force. Effective dihedral is particularly apparent in unaggressive sideward flight because the pilot must continually add lateral control as sideward velocity increases.

7. Forward-Flight Dynamic Modes

In forward flight, the dominant rigid body dynamics of a helicopter resemble those of a conventional fixed-wing airplane and include short-period, phugoid, dutch roll, and spiral modes. There is also likely to be significant coupling with flapping dynamics.
8. Correct Transition from Hover to Forward Flight

Transition effects are an important part of the piloting task when accelerating from hover into the forward flight region.

These effects are a combined result of a "dihedral effect" in the x-axis and the varying rotor downwash effect on the horizontal tail.

9. Effects of Rotor RPM Variation

Rotor RPM can affect helicopter dynamics in a number of ways, including thrust, flapping response, and heave damping.

The effects of rotor speed variation are tied, however, to the rotor-engine-governor combination. For a number of applications it may be sufficient to assume a constant rotor RPM. This will be done here.

10. Cross Coupling

A variety of cross coupling effects can be present in helicopters. Some of these such as collective-to-yaw coupling are easy-to-see, first-order phenomena. These are generally inherent in the basic dynamics if reasonable first-principles thrust and rotor models are used.

Other coupling effects may be more subtle or less predictable and should be added only where needed or desired by the simulator user. These can be inserted directly in the equations of motion as coupling terms arising from both states and controls. One should distinguish among coupling due to (i) rotor hub moments, (ii) flapping dynamics, and (iii) dihedral effects.

Cross-coupling occurs naturally when coupled rotor and hub-moment expressions are included. However, these may not suffice in matching actual cross-coupling observed in a particular design. One approach is to begin with decoupled equations then systematically add terms which provide a suitable match. (This is demonstrated in the A109 example in Appendix D).

A useful guide to cross-coupling sources is borrowed from Reference 7 and shown below in Table 2.

11. Correct Power-Off Glide

Helicopters, like fixed-wing aircraft, need to exhibit reasonable performance when power is reduced. This can be a highly complex issue if ring vortex rotor states are included. However, many handling qualities investigations can be conducted using only the normal thrust model described above but tailoring the full-down collective pitch and aerodynamic drag to yield realistic forward-velocity autorotative glide characteristics.

### B. Component Build-Up

With a specification of desired features, essential model components can then be chosen. These components contain the mechanisms which provide forces and moments, power dissipation, stability and control, and rotor dynamics.

The six components are considered necessary to provide all of the above response features are shown in Figure 2. Table 2 lists these components along with the physical features of each component and the resulting response features. In effect, this is a list of qualitative model requirements which form a starting point for detailed model design. The components and their physical elements are described and discussed individually below.
Figure 2. Basic Helicopter Math Model Components.

1. **Main rotor**

The primary component of this model is the main rotor. It is the main feature responsible for producing characteristics unique to a helicopter, in particular, a vertical thrust vector and an induced-velocity field. Other key features include rotor torque, dihedral effect, flapping stiffness (rate damping), and flapping dynamics (tip-path-plane lag).

The basis for the model used here is primarily the autogyro theory presented by Glauert in Reference 8 and extended by Lock in Reference 9. The higher order flapping dynamics as defined by Chen in Reference 6 are simplified according to the first-order model developed by Curtiss and presented in References 1 and 2.

Thrust and induced velocity are computed assuming a uniform flow distribution. As described earlier, the tip-path-plane orientation (flapping angles) are modeled as simple first order lags giving the main rotor the qualities of a force actuator with a lag. The tip-path-plane dynamics can be extended using either a coupled first-order model or a coupled second-order model based on simplification of Chen's rotor equations in Reference 6.

The main rotor model contributes largely to the power requirement feature of the model. In hover, nearly 80% of total power is absorbed by the main rotor, and, in forward flight, it is as much as 60%. In hover, rotor downwash on the fuselage also contributes to power losses.

Tip path plane and hub moment equations were rederived in a body-fixed axis system from the equations in References 3 and 6. This was done in order to avoid the real-time hover simulation problems which can arise from large instantaneous changes in the wind-axis angles for small changes in body-axis translational velocities.

It is suggested that two major components of cross coupling be avoided until the detailed model matching process is underway. One of these is the off-axis hub moments due to flapping ($L_{b1}$ and $M_{b1}$), and the second is the off-axis coupling in the tip path plane dynamics. It has been found that including these higher-order effects in a simple model does not automatically produce a high quality match to flight data.

The dihedral effect is included through the variables $db_1/dv$ and $da_1/du$ which appear in the first order flapping equations. Values can be computed using first-principles factors consisting of thrust coefficient and tip velocity. The dihedral feature is responsible for the phugoid-like modes in hover and forward flight.
The portion of $L_{b1}$ and $M_{a1}$ due to both hinge offset and rotor spring stiffness are included in a separate parameter, $dL_{dA1}$. Thus, the total flapping stiffness can be directly varied through this one parameter.

Pitch and roll mode time constants are a function of both body pitch and roll damping and rotor tip path plane lag. Control over these time constants can thus be exercised through the flapping lag as well as body aerodynamic damping.

2. Fuselage

The fuselage is represented as a virtual flat plate drag source having three dimensions. The effective aerodynamic center can be located at any position in the body reference frame. It would normally be expected to be near the geometric center.

The fuselage drag model is based on a quadratic aerodynamic form originally found in the hydrodynamics text by Lamb (Reference 10) and used extensively for airship applications by Monk (Reference 11). This form can be easily extended to account for fuselage asymmetries, lifting effects, and lift gradients.

The simple fuselage aerodynamic form presented here provides for drag in forward flight which limits maximum airspeed, drag in sideward flight, and rotor downwash impinging on the fuselage. All three of these effects are related to power losses.

3. Tail Rotor

The tail rotor component is modeled in the same manner as the main rotor except that no flapping degree of freedom is included. In effect, only Glauert's equations apply. However, thrust, induced-velocity, and power effects are correctly modeled. Normal directional control is provided through the tail rotor collective pitch variation.

4. Horizontal Tail

The horizontal tail is assumed to be primarily a lift producer, thus only the normal force component is modeled. This still provides for computation of drag resulting from induced-lift if that is desired. Finally, the effects of aerodynamic stall are included. The geometric location of the horizontal tail in the rotor flow field is used to obtain the local apparent wind component. The location of the horizontal tail provides effective static stability and elevator control.

As with the fuselage aerodynamics, a basic quadratic form is used. Two terms model the effects of camber and circulation...
lift. One additional term and conditional test is included to model the effect of stall.

5. Wing

The wing component follows the same form as the horizontal tail. In addition, the induced drag is computed in order to obtain the related power-required component which can be significant during sustained-g maneuvering.

6. Vertical Tail

The vertical tail is also similar to the horizontal tail except that it experiences the flow field produced by the tail rotor.

C. Definition of Model Equations

Once the various components of the model are defined, the equations for all the components must be expressed in a way which minimizes code and the number of parameters. The following does so according to the order of the computer program.

1. Main Rotor Thrust and Induced Velocity

The computation of thrust and induced velocity is based on a classical momentum theory equation, but with a special recursion scheme which yields a very quick convergence. The block diagram showing the thrust and induced velocity equations is given in Figure 3.

![Figure 3. Main Rotor Thrust and Induced-Velocity Block Diagram.](image-url)
The recursion relationship is based on breaking the thrust-induced velocity loop at the induced-velocity node and iterating on a solution for thrust followed by induced-velocity. This yields a fast convergence with a fixed number of iterations—about 5 is sufficient.

\[ T = (W_b - v_i) \cdot \frac{\rho \Omega R \ abcR}{4} \]

\[ v_i^2 = \sqrt{\left(\frac{\gamma^2}{2}\right)^2 + \left(\frac{T}{2 \rho A}\right)^2} - \frac{\gamma^2}{2} \]

where

\[ W_r = W_a + (a_1 + i_s) U_a - b_1 V_a \]

\[ W_b = W_r + \frac{2}{3} R \left[ \Theta_{col} + \frac{3}{4} \Theta_{twist} \right] \]

\[ \gamma^2 = U_a^2 + V_a^2 + W_r(W_r - 2v_i) \]

\[ A = \pi R^2 \]

Once induced velocity for the main rotor has been computed, one can compute the longitudinal and lateral dihedral effects of the main rotor which are, in turn, dependent on induced velocity:

\[ \frac{db_1}{dv} = \frac{da_1}{du} = \frac{2}{\Omega R} \left( \frac{6c_r}{60} \sqrt{\frac{6}{2}} \right) \]

The main rotor parameters needed for these equations are:

- \( d_{mr} \), horizontal distance of hub from c.g.
- \( h_{mr} \), hub height above the c.g.
- \( R \), rotor radius.
- \( abcR \), product of lift slope, number of blades, chord, and radius.
- \( \Theta_{twist} \), effective blade twist.
- \( \Omega \), main rotor angular rate.
2. Tail Rotor Thrust and Induced-Velocity

Thrust and induced velocity for the tail rotor is computed in the same manner as for the main rotor except that no flapping effects are included.

The parameters which define the tail rotor effects are:

- \( d^{tr} \), distance of tail rotor from c. g.
- \( h^{tr} \), height of tail rotor above c. g.
- \( r^{tr} \)
- \( (abcR)^{tr} \), product of lift slope, number of blades, chord, and radius.
- \( \Omega^{tr} \), tail rotor angular rate.

3. Fuselage Geometry and Drag

Profile drag forces are computed for the fuselage in the \( x^- \), \( y^- \), and \( z^- \) axes. These drag forces can constitute a significant portion of the overall power required and thus must be computed prior to main rotor torque. The forces are computed at the center of pressure located at the point \((X.FUS, Y.FUS, Z.FUS)\) relative to the center of gravity.

Fuselage drag forces are computed using a "quadratic aerodynamic form." In this case forces are expressed as a summation of terms formed by the product of translational velocity components in each axis. The constants in each term are the effective flat plate drag.

\[
\begin{align*}
W_{a}^{\text{fus}} & = W_{a} + v_{l} \quad \text{local w-velocity} \\
X_{\text{aero}}^{\text{fus}} & = \frac{\rho}{2} X_{\text{aero}}^{\text{fus}} U_{a} \cdot U_{a} \quad \text{drag component} \\
Y_{\text{aero}}^{\text{fus}} & = \frac{\rho}{2} Y_{\text{aero}}^{\text{fus}} V_{a} \cdot V_{a} \quad \text{side-force component} \\
Z_{\text{aero}}^{\text{fus}} & = \frac{\rho}{2} Z_{\text{aero}}^{\text{fus}} W_{a} \cdot W_{a} \quad \text{downwash component}
\end{align*}
\]
Moments due to the drag forces relative to the center of gravity are computed.

The parameters required for the fuselage are:

- \( d_{\text{fus}} \), distance of fuselage a. c. from c. g.
- \( h_{\text{fus}} \), height of fuselage a. c. from c. g.
- \( X_{\text{fus}} \), effective flat plate drag in x-axis
- \( Y_{\text{fus}} \), effective flat plate drag in y-axis
- \( Z_{\text{fus}} \), effective flat plate drag in z-axis

4. Horizontal Tail Geometry and Lift

The horizontal tail is modeled in terms of a quadratic aerodynamic form for airfoils.

The first step in computing the lift on the horizontal tail is to determine whether the surface is immersed in the rotor downwash field. This will influence the local vertical velocity vector.

The next step is to check for aerodynamic stall by comparing the force computed above with the maximum achievable at the same airspeed.

\[
W_0^N = W_0 + v_t \\
Z_{\text{aero}}^N = \frac{\rho}{2} (Z_{uu}^N U_0 U_o + Z_{uv}^N U_0 U_n) \\
\geq \frac{\rho}{2} Z_{min}^N U_o U_n
\]

local \( w \)-velocity

normal force

stall condition
Pitching moment due to the horizontal tail is computed based on the location of the aerodynamic center relative to the center of gravity.

The parameters required for horizontal tail effects are:

\[ d_{ht}, \text{ distance of horizontal tail from c.g.} \]
\[ h_{ht}, \text{ height of horizontal tail from c.g.} \]
\[ z_{uu}^{ht}, \text{ aerodynamic camber effect} \]
\[ z_{uw}^{ht}, \text{ lift slope effect} \]
\[ z_{\min}^{ht}, \text{ stall effect} \]

5. Wing Geometry and Lift

The wing is treated in the same manner as the horizontal tail. It is first checked for exposure to main rotor downwash and then for stall. For the wing, induced drag is computed in order to determine the power loss due to this effect. Lift and pitching moment for the wing are also computed.

\[
W_0^{\text{wing}} = W_0 + V_i
\text{ local } w\text{-velocity}
\]
\[
Z_{\text{wing}}^{\text{normal}} = \frac{p}{2} (Z_{uu}^{\text{wing}} U_0 + Z_{uw}^{\text{wing}} W_0^{\text{wing}})
\text{ normal force}
\]
\[
> \frac{p}{2} Z_{\text{min}}^{\text{wing}} U_0
\text{ stall condition}
\]

The power due to the induced drag of the wing is computed based on the product of force and velocity in the x-axis.

The parameters required for wing effects are:

\[ d_{\text{wing}}, \text{ distance of wing from c.g.} \]
6. Vertical Tail Geometry and Lift

The vertical tail is treated the same as the other lifting surfaces except that it is assumed out of main rotor downwash.

The parameters required for vertical tail effects are:

\[ V_{a}^{vt} = V_{a} + V_{i} \]  
local v-velocity

\[ Y_{\text{aero}}^{vt} = \frac{p}{2} (Y_{u}^{vt} U_{a} U_{0} + Y_{uv}^{vt} U_{0} V_{a}) \]  
normal force

\[ > \frac{p}{2} Y_{\text{c},u}^{vt} U_{a} U_{0} \]  
stall condition

The parameters required for vertical tail effects are:

\[ d^{vt}, \text{distance of vertical tail from c. g.} \]

\[ h^{vt}, \text{height of vertical tail from c. g.} \]

\[ Y_{uu}^{vt}, \text{aerodynamic camber effect} \]

\[ Y_{uv}^{vt}, \text{lift slope effect} \]

\[ Y_{min}^{vt}, \text{stall effect} \]
7. Total Power Required

Total power due to the main rotor, tail rotor, wing, and miscellaneous effects are summed giving the total power output by the engine.

Total power required = $P_{mr} + P_{tr} + P_{fus} + P_{wng} + P_{climb}$

$P_{mr} = P_{mr}^{\text{induced}} + P_{mr}^{\text{profile}} + P_{mr}^{\text{accessories}}$

(Note: An estimate of power required for accessories can be found in Reference 12.

$P_{mr}^{\text{induced}} = T + V_1$

$P_{mr}^{\text{profile}} = \rho/2 C_{D_0} b c R \Omega R [(\Omega R)^2 + 4.6(\frac{U_a^2 + V_1^2}{4})]$

$P_{tr} = P_{tr}^{\text{induced}} = T_{tr} V_1$

$P_{fus} = |X_{fus} U_a| + |Y_{fus} V_a| + |Z_{fus}(W_a V_1)|$

$P_{wng} = |X_{wng} U_a|$

$P_{climb} = m \cdot g \cdot h$

8. Summation of Force and Moment Equations

The first order effects of all components are summed in three force equations and three moments equations. The force due to gravity rotated through theta and phi are also included here:

$X = -m \cdot g \sin \theta + X_{mr} + X_{fus} + X_{wng}$

$Y = m \cdot g \sin \theta \cdot \cos \phi + Y_{mr} + Y_{tr} + Y_{vt}$

$Z = m \cdot g \cos \theta \cdot \cos \phi + Z_{mr} + Z_{fus} + Z_{ht} + Z_{wng}$
The equations of motion are expressed in terms of body axis accelerations so that they may be directly integrated to yield body velocities.

9. Integration and Axis Transformation

As discussed in Reference 13 the algorithm used for numerical integration of states should be carefully chosen to minimize digital effects.

The body accelerations are integrated using a second order Adams method in order to account partially for the one-frame hold between control (acceleration) input and the integrated velocity output:

\[ v_{n+1} = v_n + DT(1.5 a_n - 0.5 a_{n-1}) \]

These body velocities are then converted to earth relative velocities using a common Euler angle direction cosine transformation.

Finally, the earth velocities are integrated to obtain earth positions using a trapezoidal integration method in order to account partially for the zero-frame hold between velocity and the integrated position output:

\[ x_{n+1} = x_n + DT(0.5 v_n + 0.5 v_{n-1}) \]
10. Summary of Model Parameters

A summary of all the parameters included in this model are given below according to each model component. More detailed definitions are given in Appendix D.

III. Model Matching and Estimation Procedures

In order to demonstrate model matching and estimation procedures, a model of the Bell AH-1S Cobra is developed. The actual code for this example version along with a list of symbols and a table of associated input parameters are presented in Appendices A, B, and C. An example involving the matching of actual flight data is presented in Appendix D for the Augusta Model 109 helicopter.

The primary sources which are used in the Cobra example are the flight manual (Reference 14), a manufacturer's stability and control package (Reference 15), a volume of Jane's (Reference 16), and a flight dynamics data report (Reference 17). Other useful references include the USAF Stability and Control Datcom (Reference 18), the U. S. Army Engineering Design Handbook (Reference 19) and the previously cited Stepniewski and Keyes reference.

In this section the method is described for determining the individual components of the AH-1S and its associated parameters. There are 44 total parameters needed for this model. 22 of these are simple geometrical variables which can be easily obtained from scale drawings, from aircraft manuals, or even estimated from a picture of the aircraft.

A. Mass, Loading, and Geometry Data

A substantial portion of the data required is either directly obtainable geometric data or common mass and loading data.

1. Geometric Data

Geometric parameters are easily obtained from aircraft drawings or reference literature. Figure 4, taken from the flight manual, provides a basis for geometric information. Note that positions of all major components are given relative to the manufacturer's reference system (fuselage stations, waterlines, and buttlines).

Explicit positions can be obtained for some features such as main rotor hub position and tail rotor hub. For airfoils it is generally sufficient to estimate and use the positions for one-quarter mean aerodynamic chord. The fuselage aerodynamic center is less clearly defined and must be estimated depending upon the shape. Appendages such as tail boom and landing gear can be considered in estimating the fuselage aerodynamic center.

Figure 6-1. Helicopter Station Diagram.
2. Mass and Loading Data

Values for normal operating gross weight and center of gravity are typically obtained from operating manuals. An example is shown in Figure 5. Specific choices will depend upon the general loading condition of interest. Here an intermediate loading is chosen which also corresponds to other available data.

Inertial data from the Reference 15 stability and control report are given in Table 4. While these do not correspond exactly to the loading chosen above, they can be easily rescaled by assuming a constant radius of gyration in each axis.

B. Propulsion Data

Required propulsion data include power available for given operating conditions. These data can be found in Jane's under the appropriate propulsion system manufacturer as illustrated in Table 5. The specific information of interest here is the maximum continuous power rating for the AVCO Lycoming T53-L-703 gas turbine engine.

Other information needed consists of an approximate breakdown of power, including that due to accessories. Data from the Stepniewski and Keyes source are given in Table 6. These data will be used to estimate power losses from the computed power required by each of the components listed previously.

The basis for torque (power) available under various operating conditions is given in Figure 6. (Percent torque is assumed equal to percent power for the normal operating rpm—324 in this case.)

C. Rotor Data

Rotor system characteristics consist of geometric, aerodynamic, and operating condition features. Most of the geometric data including size and number of blades and hub center are easily found in flight manuals. Operating conditions, namely the normal operating rpm, are likewise obtained.

The main aerodynamic parameters include the effective section lift curve slope and profile drag coefficient. Commonly accepted values of 5.7 and .006, respectively, are sufficient starting points.

The most crucial rotor parameters, however, are those relating to the effective flapping stiffness or hinge offset. These data are generally found only in manufacturers design reports. Of course in the case of a simple tethering rotors the effective hinge offset is zero. Articulated rotor designs are also fairly easy to represent as long as the geometric hinge offset is known. The most difficult variety to model is the hingeless rotor since both an effective hinge offset and flapping spring must be determined.

Useful auxiliary information for modeling the rotor system is response data which provides direct indication of the unaugmented pitch and roll damping.

D. Aerodynamic Features

Aside from the rotor system aerodynamics, parameters must be estimated for the airfoil and fuselage components. The techniques for doing so are common and require little effort. If manufacturer’s stability and control data are available these calculations are trivial. Otherwise, one can refer to estimation handbooks such as the USAF DATCOM (Reference 18).

Airfoil lift parameters involve three main features: camber and incidence circulation lift, and stall. The first two are highly dependent upon geometry and the third on maximum lifting performance.

Relationships which are needed for setting parameters involve the quadratic aerodynamic parameters and the more common non-dimensional aerodynamic coefficients. These are given below for use in the estimation procedures described in Figure 7. The equations are for the horizontal tail, but the other airfoil surfaces are similar.

Estimates typical for airfoils:
$z_{uu} = -S_{ht} C_{L_0}^h$; $C_{L_0}$ is set by both camber and incidence of the airfoil.

$z_{uw} = -S_{ht} C_{L_x}^h$; note that $C_{L_x} \approx \frac{2\pi R}{R+2}$.

$z_{\min} = -S_{ht} C_{L_{\max}}^h$; typical values are 1.5 to 3 depending upon aspect ratio.

Similarly, fuselage drag estimates can be made for each of the three axes using available drag data.

Estimates typical for fuselage drag:

$$X_{uu}^{fus} = -S_{fus}^f C_D$$

where $S_{fus}^f$ is the projected frontal area

and $C_D$ can be estimated using numerous textbook tabulations of 3-dimensional drag. This will vary for each axis.
1. WING:
   span = 10.75'
   chord = 3.0'
   area = 32.25 ft²
   aspect ratio = 3
   \( C_{L\alpha} = \frac{2\pi R}{R + 2} = 5 \) (based on \( \alpha = 14^\circ \), \( C_{L0} = 1.2 \), assume \( C_{L_{max}} = 2 \))

2. HORIZONTAL TAIL:
   span = 7'
   chord = 2.25'
   area = 16 ft²
   aspect ratio = 3
   \( C_{L\alpha} = 5 \)

3. VERTICAL TAIL:
   span = 5'
   chord = 3.3'
   area = 17 ft²
   aspect ratio = 1.5
   \( C_{L\alpha} = 2.7 \) (assume \( C_{L_{max}} = 3 \))

4. FUSELAGE:
   assumed drag coefficients:
   front, 0.2
   side, 0.2
   plan, 0.7

Figure 1. Basis for Initial Estimates of Aerodynamic Parameters.
E. Hover Performance

The parameters listed above provide a starting point for the math model. Additional flight manual and available flight data will serve to make refinements in model response and performance characteristics.

The first adjustment of model parameters can be made based on the flight manual hover performance as shown in Figure 8. Here the percent maximum torque is given for a specific hover condition.

The factors which can be adjusted to achieve a good match are the power losses due to accessories, downwash on the fuselage and horizontal airfoils, or main rotor induced velocity factor (if included).
Figure 9. Basis for Hover Power Required.
F. Forward Flight Data

Up to this point model adjustments have centered on the main rotor system since body drag has been low due to the hover condition. With the consideration of forward flight the fuselage now plays a major role in limiting maximum speed and climb performance.

The main set of data useful for adjusting fuselage drag are given in Figure 9 from the flight manual. Note that the primary information is the torque required as a function of flight condition and loading. The two main features on this plot are the maximum speed at continuous operating torque and the torque and speed for level flight at minimum power.

Additional information is given in Figure 10 with the maximum rate of climb corresponding to an increase in torque.

Finally in Figure 11 data are given for the maximum glide and minimum rate of descent. These are useful for setting the effective full-down collective pitch stop.
Figure 10. Basis for Forward Flight Speeds and Power Required.
Figure II. Basis for Max Rate of Climb Speed and Power Required.
Figure 12. Basis for Max Glide Speed and Descent Angle.
As a final note, the process of tuning model parameters should not be done without careful consideration of all secondary effects. The best policy is to avoid making anything other than simple direct first-principles corrections. There is substantial redundancy in some of the data shown here, and it is not possible to achieve perfect matches in all respects. One needs to exercise judgment in the degree of accuracy required as a function of the model application.
IV. Checkout Procedures

A. General

As discussed earlier, model complexity can hamper the thoroughness of simulator computer program implementation and checking. However, the model presented here can be fully checked with reasonable effort. This is due to the small number of model constants and degrees of freedom, and minimal program branching. The recommended checking procedure involves the following elements:

- Use of an independent operating program.
- Verification of trim points.
- Verification of state transitions through n steps.
- Overlay of time histories.
- Identification of dominant response modes.

Some of these steps are redundant but nevertheless serve to build confidence in the correctness of the math model implementation at only minimal added cost. The following is a brief discussion of each element.

B. Discussion of Checkout Procedure Elements

1. Independent Operating Program

As a general rule, math model checkout should be accomplished using an independent implementation and check source. Furthermore, not only should an independent program be used but also an independent computer.

This math model form enables the user to develop a math model version on a small desktop microcomputer and run complete sets of check cases well in advance of using the simulator computer facilities.

The specific computer system used to develop and run this math model consisted of a Compaq 286 desktop computer with 640K working memory running Microsoft Basic. Only an interpreter mode was used although a Basic compiler is available. The interpreter permits a highly efficient interaction between the model developer and the computer system.
2. Trim Point Verification

A check of static trim points gives an initial indication of correct model implementation. The full operating envelope can be covered with just a few cases and possible discrepancies isolated to airspeed, vertical velocity, or controls. A cursory check of suspected parameters or component equations can usually lead to simple corrections. Trim solutions should be correct prior to proceeding to the next item.

A sample of the trim solution printout is given in Figure 12. This same format is displayed during the trimming process so that one can observe whether there are difficulties in iterating on a solution.

```
TRIM CALCULATIONS

Pdot = 1.05E+00  DC = 15.7
Qdot = -1.44E-01  al = 1.3
Rdot = 3.28E-03  b1 = -2.1

VT = 0.0
Hit (G) to freeze trim anytime

Trimmed: Hit PRTSC to make hard copy
Hit RETURN to continue
```

Figure 13. Sample of Trim Point Printout.
3. State Transition Verification

Given that static solutions are valid, the dynamic response characteristics should be examined next. Correct operation is indicated by tracking several discrete state variable transitions and comparing with independently obtained check values. This is made feasible by restricting the number of degrees of freedom and levels of numerical integration. For example, only about six transitions for each control variable are needed to excite each term in the model equations.

In order to thoroughly check state transitions, a table overlay is recommended. This is accomplished by duplicating the state transition printout format of the checkout computer with that of the simulator computer. The original checks can be printed on transparencies then directly overlaid with the simulator printout.

Examples of the state transition checks are given in Table...

Table 7, Concluded.
4. Time History Overlays

In theory the combination of static and state transition checks should be sufficient to demonstrate agreement with the independent model implementation. However, additional confidence is gained by selecting several time history cases to overlay. These can be supplemented by checking dominant response modes based on transfer function solutions from the original independent check model.

Useful time histories to consider are angular rates for both on- and off-axes for a given control input. This checks both the dominant response modes and the amount of off-axis cross coupling. Examples are shown in Figure 13 corresponding to the previous check information.
Figure 13. Examples of Time Histories to be Used for Overlays.
5. Dominant Response Identification

It is also useful to supplement the above checks with a comparison of identified dominant response features from the simulator computer with those features observed or computed from the independent checkout version. This is particularly important for handling qualities investigations.

Dominant modes are examined by exciting an axis with the corresponding direct control and scaling the appropriate first- or second-order response features from the respective motion traces. The on-axis traces presented earlier in Figure 13 serve this purpose for extracting short-term pitch response information.
V. Model Extensions and Refinements

The example which has been presented above can be modified in a number of ways in order to address specific simulation needs. The above math model can be either simplified or made more sophisticated. The following is a discussion of some possible extensions and refinements.

A. Flight Control System

There is no flight control system included in the above model other than conventional aerodynamic interfaces such as cyclic, collective, and tail rotor controls. Addition of a flight control system requires definition of relationships between the cockpit, manipulator, and the above aerodynamic controls plus any stability and control augmentation systems.

As with the basic airframe math model, definition of flight controls can be done with a wide range of computational complexity. However, the same considerations can be applied in order to match the level of complexity with user utility. The main question is to what degree can the simulator pilot observe or be influenced by math model intricacies.

B. Engine Governor

This aspect of the helicopter math model can be important for tasks involving maneuvering or aggressive control of collective pitch.

The above math model is designed to accommodate an engine governor system since rotor speed is explicit in the equations. It is necessary only to add appropriate engine governor equations of motion prior to computation of the main rotor thrust.

In general, only a second-order engine governor response is required in order to handle the effective spring-mass-damper action of the main rotor combined with the propulsion system and governor control laws. An adequate model is described in Reference 20.

C. Ground Effect

The modeling of ground effect can be important for tasks involving hover under marginal performance conditions. Again, the computational complexity of such models can vary widely.

It is recommended that, as a first cut, ground effect be modeled as an induced-velocity efficiency factor which primarily affects the thrust and power required to hover. This efficiency factor can be adequately modeled as an exponential function of altitude. The exponential scale height and magnitude is easily quantified from the flight manual hover performance shown earlier in Figure 8.
D. Dynamic Inflow

For certain vertical response applications it may be important to model the effective lag in thrust due to a collective pitch change. This is typically a first-order lag in the range of 10 to 15 rad/sec and varies with the sign of the collective pitch change.

This effect can be modeled by setting a first-order lag on the calculation of thrust and induced velocity. Reference 21 can be consulted for guidance in setting values. Other forces and moments can also be affected by dynamic inflow as described in Reference 22.

E. Higher-Order Flapping, Coning, and Lead-Lag Dynamics

Higher order rotor system dynamics may be of interest when examining flight control system schemes or certain vibrational effects. However the modes can easily be outside the computational ability of the simulator or highly distorted by the motion system. Thus is crucial for the modeler to analyze computational requirements relative to capabilities.

</table>
DC(3) Roll control, $A_1$, (rad).

DC(4) Tail rotor collective pitch angle (rad).

DENS.RATIO Density ratio.

D.FUS Fuselage horizontal position of aerodynamic center (ft).

D.FW Position of downwash on fuselage (ft).

D.HT Horizontal tail aerodynamic center relative to c. g. (ft).

D.HUB Hub horizontal position relative to c. g. (ft).

DL.DBI Direct flapping stiffness (rad/sec²).

DL.DAI Off-axis flapping stiffness (rad/sec²).

D.TR Tail rotor horizontal position (ft).

EPS.HT Downwash field on horizontal tail relative to induced velocity.

F(1) Force and moment vector.

F(1) Total x-force component (lb).

F(2) Total y-force component (lb).

F(3) Total z-force component (lb).

F(4) Total rolling moment component (ft-lb).

F(5) Total pitching moment component (ft-lb).

F(6) Total yawing moment component (ft-lb).

F(7) Pitch axis flapping angle, $a_1$, (rad).

F(8) Roll axis flapping angle, $b_1$, (rad).

FR.MR Effective frontal area of main rotor (ft²).

FR.TR Effective frontal area of tail rotor (ft²).

GAM.OM.16 One-sixteenth the product of Lock Number and rotor angular rate (rad/sec).

GV(7) Longitudinal tip-path-plane angular rate (rad/sec).

GV(8) Lateral tip-path-plane angular rate (rad/sec).

H.FUS Fuselage vertical position of aerodynamic center relative to c. g. (ft).

H.HUB Hub vertical position relative to c. g. (ft).

H.TR Tail rotor vertical position relative to c. g. (ft).
**HP.LOSS**  Net power loss due to transmission, accessories, etc.

**IS**  Main rotor shaft incidence (rad).

**ITB**  Inverse tip-path-plane lag (rad/sec).

**ITB2.OM**  ITB squared over OMEGA.MR (rad/sec).

**KC**  Flapping coupling factor.

**KIND**  Induced velocity factor.

**L.FUS**  Fuselage aerodynamic rolling moment (ft-lb).

**L.MR**  Main rotor rolling moment (ft-lb).

**L.TR**  Tail rotor rolling moment (ft-lb).

**L.VT**  Vertical tail rolling moment (ft-lb).

**M**  Vehicle mass (slug).

**M.FUS**  Fuselage aerodynamic pitching moment (ft-lb).

**M.HT**  Horizontal tail pitching moment (ft-lb).

**M.MR**  Main rotor pitching moment (ft-lb).

**M.WN**  Wing pitching moment (ft-lb).

**N.FUS**  Fuselage aerodynamic yawing moment (ft-lb).

**N.MR**  Main rotor yawing moment or torque (ft-lb).

**N.TR**  Tail rotor yawing moment (ft-lb).

**N.VT**  Vertical tail yawing moment (ft-lb).

**OMEGA.MR**  Main rotor angular velocity (rad/sec).

**OMEGA.TR**  Tail rotor angular velocity (rad/sec).

**P.CLIMB**  Power loss due to change in potential energy (ft-lb/sec).

**P.INDUCED.MR**  Power loss due to main rotor induced velocity (ft-lb/sec).

**P.INDUCED.TR**  Power loss due to tail rotor induced velocity (ft-lb/sec).

**P.PARASITE**  Power loss due to fuselage parasite drag (ft-lb/sec).

**P.PROFILE.MR**  Power loss due to main rotor profile drag (ft-lb/sec).

**POWER.FUS**  Power loss from fuselage aerodynamic drag (ft-lb/sec).

**POWER.MR**  Power loss from main rotor and fuselage (ft-lb/sec).
POWER.TR  Power loss from tail rotor (ft-lb/sec).
POWER.WN  Power loss from wing induced drag (ft-lb/sec).
POWER.ROTOR.MR  Power loss from main rotor (ft-lb/sec).
PRESS.RATIO  Pressure ratio.
R2  One half RHO.
RHO  Air density (slug/ft²).
R.MR  Main rotor radius (ft).
R.TR  Tail rotor radius (ft).
S4  Sin of roll Euler angle.
S5  Sin of pitch Euler angle.
S6  Sin of heading angle.
ST  Numerical integration step size (sec).
TEMP.RATIO  Temperature ratio.
TWST.MR  Main rotor twist (rad).
TWST.TR  Tail rotor twist (rad).
THRUST.MR  Main rotor thrust (lb).
THRUST.TR  Tail rotor thrust (lb).

X.WN    Wing x-force (lb).

XU.FUS  Fuselage parasite drag force (ft²).
Y.FUS   Fuselage y-force (lb).
Y.GRAV  Gravity y-force (lb).
Y.MIN.VT Vertical tail stall factor (ft²).
Y.MR    Main rotor y-force (lb).
Y.TR   Tail rotor y-force (lb).

YU.VT   Vertical tail profile drag factor (ft²).
YUV.VT  Vertical tail circulation lift factor (ft²).
Y.VT    Vertical tail y-force (lb).

YV.FUS  Fuselage sideward drag factor (ft²).
Z.MIN.HT Horizontal tail stall factor (ft²).
ZMIN.WN Wing stall factor (ft²).
Z.FUS   Fuselage z-force (lb).
Z.GRAV  Gravity z-force (lb).
Z-HT    Horizontal tail z-force (lb).

ZUU.HT  Horizontal tail profile drag factor (ft²).
ZUU.WN  Wing profile drag factor (ft²).
ZUW.HT  Horizontal tail circulation lift factor (ft²).
ZUW.WN  Wing circulation lift factor (ft²).
ZWW.FUS  Fuselage quadratic drag coefficient along z-axis (ft²).
APPENDIX C
DEFINITION OF PROGRAM INPUT FILE

The following describes the input format needed to define the math model for a specific helicopter. The specific values given correspond to the AH-1S example. Individual entries are discussed in detail in Appendix D.

C-1
APPENDIX D
MATH MODEL MATCHING PROCESS FOR AUGUSTA A109 II HELICOPTER

This appendix describes a minimum-complexity math model version of the Augusta A109 II helicopter based on available flight data and flight manual information. The data were furnished by the Army Aeroflightdynamics Directorate in order to provide an illustration of the parameter matching procedure and verification of the resulting math model.

It is believed that the results of this modeling process are sufficiently good to be used as the basis of a lateral control handling qualities experiment such as that performed under this contract.

The general procedure followed was first to quantify the basic math model form using engineering data provided by the helicopter manufacturer. The second step was to adjust parameters in order to match trim data from flight and to add certain nonlinear characteristics such as downwash on tail and fuselage. The final step was to match dynamic response cases adjusting rotor model parameters. Details of the matching procedure are presented below.

1. Initial Quantification of Model Parameters

The first step was to set up the main data file for the math model using all available engineering data. In this case a fairly complete array of these data were supplied by the manufacturer. The following paragraphs present the initial quantification of parameters for each of the model components and a short discussion of the basis for quantification.

**Loading Parameters**

FS.CG, WL.CG, WT

132.7 in, 38.5 in, 5401 lb

"FS.CG" is the location of the center of gravity in the fuselage reference system in inches from the zero fuselage station. For the A109 this can be found in the flight manual but must be converted from millimeters.

"WL.CG" is the vertical center of gravity location in inches above the zero waterline. Without a specific value, this can be estimated as approximately at the level of the engine. However it is important to determine this quantity as accurately as possible since a significant portion of flapping stiffness (thus
pitch and roll damping) results from the vertical offset of the rotor hub from the vertical center of gravity.

"WT" is the gross weight of the aircraft in pounds. A representative value can be picked from the flight manual loading envelope diagram, however a fairly accurate weight should be available for any given set of flight data.

\[
\begin{align*}
IX, & \quad IY, & \quad IZ, & \quad IXZ \\
1590 \text{ slug-ft}^2, & \quad 6761 \text{ slug-ft}^2, & \quad 6407 \text{ slug-ft}^2, & \quad 598 \text{ slug-ft}^2
\end{align*}
\]

"IX," "IY," "IZ," and "IXZ" are the moments of inertia about the center of gravity in the "body" or fuselage reference line axis system. The first three are essential to the math model. IXZ can be neglected but an effect can be seen in yaw response due to roll axis inputs. It should be recognized that moments of inertia often cannot be measured accurately and can therefore be subject to modification in order to match flight data. For the A109 the value of IX was reduced from that shown above in order to match the primary roll damping mode.

**Main Rotor Parameters**

\[
\begin{align*}
\text{FS.HUB,} & \quad \text{WL.HUB,} & \quad \text{IS,} & \quad \text{E.MR,} & \quad \text{I.B,} \\
132.4 \text{ in,} & \quad 98.2 \text{ in,} & \quad 0.11 \text{ rad,} & \quad 0.5 \text{ ft,} & \quad 212 \text{ slug-ft}^2
\end{align*}
\]

"FS.HUB" is the fuselage reference system location of the main rotor hub measured aft of the zero fuselage station.

"WL.HUB" is the corresponding waterline location of the main rotor hub.

"IS" is the main rotor shaft tilt forward of vertical in the fuselage reference system and measured in radians.

"E.MR" is the geometric main rotor flapping hinge offset for an articulated rotor or the effective hinge offset for a rigid rotor. Any empirical adjustment of this parameter should be done with care. In general, for teetering and articulated hubs, variation of the roll moment of inertia is probably easier to justify than the geometric flapping hinge offset.

"I.B" is the flapping inertia of a single blade about the flapping hinge.
R.MR, A.MR, RPM.MR, CDO, B.MR,
18 ft, 6/rad, 385 rpm, 0.010, 4 blades

"R.MR" is the actual main rotor diameter in ft.

"A.MR" is the effective lift-curve-slope of the main rotor in units of non-dimensional lift coefficient per unit radian of angle of attack. Values of 5.7 or 6 are commonly used.

"RPM.MR" is the nominal angular velocity of the main rotor in units of revolutions per minute. This can ordinarily be found in a flight manual.

"CDO" is the effective profile drag for the main rotor blade cross section. Values of 0.010 or 0.012 are commonly used, but this can be adjusted in order to fit power required data, especially in hovering flight.

"B.MR" is the number of blades in the main rotor array.

C.MR, TWST.MR, K1
1.10 ft, -.105 rad, .096

"C.MR" is the blade chord in ft.

"TWST.MR" is the effective blade twist in radians.

"K1" is the tangent of delta-3, the effective pitch-flap coupling based on flapping hinge geometry. Although the above value was given for the A109, the effect was ultimately neglected in matching pitch and roll cross-coupling effects.

**Fuselage Parameters**

FS.FUS, WL.FUS, XUU.FUS, YVV.FUS, ZWW.FUS
132 in, 38 in, -10.8 ft², -167 ft², -85 ft²

"FS.FUS" is the fuselage station corresponding to the effective center of pressure in the vertical axis. Here it was nominally set equal to the main rotor hub position.

"WL.FUS" is the waterline for the center of pressure in the longitudinal axis. It can be adjusted to account for hub drag as well as that of the fuselage itself. In this case it was set at the vertical center of gravity.
"XUU.FUS" is the effective frontal area corresponding to profile drag in the x-axis. The value used here was provided by the manufacturer.

"YVV.FUS" is the effective side area for sideward flight, that is, sideslip equal to 90 deg. Again it was provided by the manufacturer.

"ZWW.FUS" is the effective planview area for vertical flight, i.e., angle of attack equal to 90 deg. It affects the power required to hover and is used in conjunction with pitching moment due to airspeed changes.

Wing Parameters

FS.WN, WL.WN, ZUU.WN, ZUW.WN, ZMAX.WN, B.WN

000 in, 00 in, 000 ft², 0000 ft², 000 ft², 1 ft

The A109 does not have a wing, thus zeros were set for all values except the span which needs any arbitrary non-zero value to avoid division by zero. All the individual values can however be found or estimated similarly to those for the horizontal tail.

Horizontal Tail Parameters

FS.HT, WL.HT, ZUU.HT, ZUW.HT, ZMAX.HT

330 in, 54 in, .4 ft², -34 ft², -22 ft²

"FS.HT" is the effective aerodynamic center of the horizontal tail in inches from the reference fuselage station. It can be estimated as the quarter mean aerodynamic chord based on engineering data or on a planview of the aircraft.

"WL.HT" is the effective vertical location of the horizontal tail. The value used is important in computing the position of the main rotor downwash field as airspeed is varied.

"ZUU.HT" is the effective lift per unit dynamic pressure at zero angle of attack relative to the fuselage reference system. This value used is important in establishing the trim pitch angle at high forward velocities.

"ZUW.HT" is the effective variation in circulation lift and can be estimated as the negative product of lift-curve-slope and surface area.
**Vertical Fin Parameters**

FS.VT, WL.VT, YUU.VT, YUV.VT, YMAX.VT

380 in, 80 in, 3.3 ft\(^2\), -47 ft\(^2\), -17 ft\(^2\)

"FS.VT" is the fuselage station for the effective aerodynamic center of the vertical fin.

"WL.VT" is the vertical position of the vertical fin aerodynamic center.

"YUU.VT" is the net y-force per unit dynamic pressure for zero sideslip. This arises either from vertical fin camber or incidence.

"YUV.VT" is the sideforce arising from a side-velocity component and is approximately equal to the lift-curve slope time the net fin area.

"YMAX.VT" sets the maximum sideforce generated by the vertical tail at stall.

**Tail Rotor Parameters**

FS.TR, WL.TR, R.TR, A.TR, SOL.TR, RPM.TR, TWST.TR

391 in, 70 in, 3.1 ft, 3/rad, .134, 2080 rpm, -.137 rad

"FS.TR" and "WL.TR" represent the center of the tail rotor hub in the fuselage reference system.

"R.TR" is the radius of the tail rotor in ft.

"A.TR" is the effective lift-curve-slope of the tail rotor and can be set equal to that of the main rotor. It can be adjusted downward in order to account for interference effects with the vertical fin. In this case it was reduced by one half in order to match pedal trim data as discussed below.

"SOL.TR" is the solidity of the tail rotor, i. e., the ratio of actual blade area to disk area.

"RPM.TR" is the angular velocity of the tail rotor in terms of revolutions per minute.

"TWST.TR" is the effective twist of the tail rotor blade.
2. Model Adjustments Needed to Match Static Trim Data

Several model parameters and functions were adjusted in order to produce good static trim matches. This was important in establishing realistic attitudes, control deflections, and power requirements.

For the A109 those adjustments found necessary included:

- A tail rotor efficiency factor of 0.5 in order to account for vertical fin interference effects.
- A triangular main rotor downwash field superimposed on the horizontal tail vertical velocity and displaced 1 ft rearward.
- A magnification of the dihedral effect at low speeds individually set for the lateral and longitudinal axes.
- A shift in the planview center of pressure such that the downwash on the fuselage provides a pitching moment proportional to airspeed.

Tail Rotor Effectiveness

The first adjustment was made by changing "A. TR" from a nominal value of 6/rad to 3/rad. This was done on the basis of matching the pedal deflection (i.e., tail rotor collective pitch), especially at low speed and hover. The effect was applied directly in the tail rotor thrust equation wherein "A. TR" appears.

\[
\text{THRUST.TR} = (vB.TR - vL.TR) * \Omega.MR.R * \rho.A.TR.SOL.TR * \pi.R.TR.R.TR/4
\]

Triangular Induced-Velocity Field

The second adjustment consisted of assuming a triangular induced velocity field with a magnitude of 2 at the rotor tip and zero at the hub. This can be justified by observing measured downwash field data such as presented by Heyson and Katzoff in NACA Report 1319. This effect is crucial to portraying the large change in pitch attitude between zero airspeed and 20 kt rearward. The program instructions affected are given below:

\[
\]
(position where edge of downwash passes through plane of horizontal tail)
D.DW = D.DW + 1
(shift of D.DW by one foot in order to match speed where downwash on tail effect is seen in trim data)

IF (D.DW>0 AND D.DW<R.MR) THEN EPS.HT = 2*(1-D.DW/R.MR)
ELSE EPS.HT = 0
(triangular downwash if D.DW is negative)

WA.HT = VA(3) - EPS.HT*VI.MR + D.HT*VA(5) : local z-vel at h.t.
(apperance of downwash effect in computation of relative z velocity component at horizontal tail)

Dihedral Magnification at Low Speed

The third adjustment consisted of magnifying the effective dihedral effect at very low speeds when the rotor wake interacts with the fuselage. This enhanced dihedral effect could be seen directly in the cyclic control gradient with respect to forward speed and side velocity.

The model equations affected are limited to the rotor flapping equations. Below a speed of VTRANS the computed parameters daldu and dbldv are multiplied by 3 and 2, respectively. The values are empirical and based on cyclic trim data. VTRANS was set at 30 kt based on the large change in stick trim observed at that point. The program statements involved are shown below:

IF VA(1) < VTRANS THEN WAKE.FN = 1 ELSE WAKE.FN = 0
(rotor wake effects are added to the effective tip-path-plane dihedral when WAKE.FN = 1, i.e., below and airspeed equal to VTRANS)

A.SUM = GV(8)-DC(2)+KC*GV(7)+DB1DV*VA(2)*(1+WAKE.FN)
( i.e., bl - A1 + e.al + db1/dv .V )

B.SUM = GV(7)+DC(3)-KC*GV(8)+DA1DU*VA(1)*(1+2*WAKE.FN)
( i.e., a1 + B1 - e.bl + dal/du .U )

GR(7) = -ITB*B.SUM - ITB2.OM*A.SUM - VA(5)
( i.e., a1.dot = ... )

GR(8) = -ITB*A.SUM + ITB2.OM*B.SUM - VA(4)
( i.e., b1.dot = ... )

Downwash Center of Pressure on Fuselage

The fourth and final adjustment needed to match trim data is the shift of downwash center of pressure on the fuselage as speed varies. This affects not only the longitudinal cyclic to trim but also the trim pitch attitude.
The approach was to compute an effective wake position in the plane of the fuselage similar to that computed for the horizontal tail. This position was then used in the pitching moment equation along with an empirical magnification factor. The net effect is a change in fuselage pitching moment with forward speed.

The program instructions affected are:

\[
WA.FUS = VA(3) - VI.MR
\]

(computed net downwash on fuselage, i.e., \( W - V_i \))

\[
D.FW = \left( \frac{VA(1)}{-WA.FUS} \right) \left(H.HUB-H.FUS\right) - (D.FUS-D.HUB)
\]

(computed position of downwash at fuselage waterline as airspeed varies)

\[
D.FW = 3 \times D.FW
\]

(empirical magnification of a.c. shift used to match trim data)

\[
Z.FUS = R2 \times ZWW.FUS \times \text{ABS}(WA.FUS) \times WA.FUS
\]

(z-force resulting from downwash on fuselage)

\[
M.FUS = Z.FUS \times D.FW - X.FUS \times H.FUS
\]

(pitching moment due to x- and z-forces acting at their respective aerodynamic centers)

The resulting math model trim characteristics are compared with the A109 flight data in the following pages.

D-14

The final step in the model matching process was the adjustment in the model to account for features seen in both the primary on-axis response as well as cross-coupling effects.

The adjustment of dynamic response features was limited only to pitch and roll response in hover. Other axes and flight conditions would be addressed in a similar manner.

In the case of the A109 it was found that by removing cross-coupling in flapping and hub moment equations a reasonably good match could be achieved for the pitch and roll axes with only minor adjustment of moments of inertia.

Roll Inertia Reduction

The dominant roll-damping mode was matched closely by varying the lateral flapping stiffness via a reduction in the roll moment of intertia. This was considered preferable to increasing the flapping hinge offset since the latter would also affect the pitch response.

The value of IX in the data input file was reduced from 1590 to 1300 slug-ft^2.

Removal of Rotor Flap Cross-Coupling

One element of pitch response due to a roll input can be attributed to the cross-coupling in the rotor flapping equations. In this case it was found that decoupled flapping provided a better match to flight data thus the simplification was made.

The coupled first-order flap equations were decoupled by simply by recomputing the values of "ITB" and "ITB2.OM." Thus the primary flapping response consists only of a first-order lag as described in Reference 1.

This change is accomplished by setting:

\[ \text{ITB} = \text{GAM.OM.16} \]

and \[ \text{ITB2.OM} = 0 \]

Elimination of Hub-Moment Cross-Coupling
The aerodynamic cross-coupling represented by DL.DOi was also set equal to zero in order to further suppress pitch cross-coupling due to roll as seen in flight data.

**Removal of Delta-3 Effect**

In order to maintain consistency of model complexity following the above simplifications, the Delta-3 effect as represented by the parameter "KI" was also set to zero.

**Adjustment of Cross-Axis Inertia**

The effect of an inclined principal axis of inertia could be seen readily in the short-term yaw response following a roll input. An increase in $I_{xz}$ from 598 to 800 slug-ft$^2$ provided a slightly better match to flight data.

**Adjustment of Cyclic Control Phasing**

There was some evidence of cyclic control phasing in the A109 although control system geometry indicated none. First, inspection of swashplate angle records for pitch and roll inputs showed minor off-axis inputs which were generally consistent with the cross-coupling response which followed. Also there was a direct measurement of a nearly 10 deg steady lead-lag component which, depending upon the hub pitch control geometry, could contribute to a cyclic control phase effect.

The results of the dynamic response adjustments for pitch and roll inputs in hover are shown in the following pages.

ORIGINAL PAGE IS OF POOR QUALITY
An example of a minimal complexity simulation helicopter math model is presented. Motivating factors are the computational delays, cost, and inflexibility of the very sophisticated math models now in common use. A helicopter model form is given which addresses each of these factors and provides better engineering understanding of the specific handling qualities features which are apparent to the simulator pilot. The technical approach begins with specification of features which are to be modeled followed by a build-up of individual vehicle components and definition of equations. Model matching and estimation procedures are given which enable the modeling of specific helicopters from basic data sources such as flight manuals. Checkout procedures are given which provide for total model validation. A number of possible model extensions and refinements are discussed. Math model computer programs are defined and listed.
