Abstract

A computational procedure is presented for the geometrically nonlinear analysis of aircraft tires. The Space Shuttle orbiter nose-gear tire was modeled through use of a two-dimensional laminated anisotropic shell theory with the effects of variation in material and geometric parameters included. The four key elements of the procedure are (1) semi-analytic finite elements in which the shell variables are represented by Fourier series in the circumferential direction and piecewise polynomials in the meridional direction; (2) a mixed formulation with the fundamental unknowns consisting of strain parameters, stress-resultant parameters, and generalized displacements; (3) multilevel operator splitting to effect successive simplifications and to uncouple the equations associated with different Fourier harmonics; and (4) multilevel iterative procedures and reduction techniques to generate the response of the shell. Numerical results of the Space Shuttle orbiter nose-gear tire model are compared with experimental measurements of the tire subjected to inflation loading.

Introduction

Because of the axial symmetry of undeformed tires, it is desirable in their modeling and analysis to exploit the substantial capability that currently exists for the numerical analysis of shells of revolution. The most commonly used approach for the analysis of shells of revolution is based on the representation of the shell variables and loads by a Fourier series in the circumferential coordinate $\theta$, combined with the use of a numerical discretization technique (such as finite elements, finite differences, or numerical integration) in the meridional direction. (See, for example, refs. 1 to 7.) Such an approach has the major advantages of accuracy and stability (i.e., no locking or spurious modes) over approaches which use two-dimensional shell elements. Moreover, for linear problems of shells with uniform circumferential properties, the Fourier series representation permits separation of variables and the equations uncouple in harmonics. However, when applied to the analysis of tires the approach has the following drawbacks, which can make the computational cost of the geometrically nonlinear analysis of tires quite expensive:

1. For geometrically nonlinear problems, the unknowns associated with different harmonics are coupled (see refs. 8 and 9).
2. Even for linear problems, because of the anisotropy of the cord-tire composites, the symmetric and antisymmetric responses (with respect to $\theta = 0$) associated with each harmonic are coupled.
3. For localized loading (e.g., contact pressure on the tire), a large number of harmonics are needed to accurately predict the response.

Research on tire modeling and analysis at NASA Langley Research Center has focused on developing accurate and cost-effective strategies for predicting tire response. Included in the research is the development of analysis procedures for substantial reduction of the computational expense resulting from the harmonic and anisotropic couplings (items 1 and 2) and the generation of the response associated with large numbers of harmonics (item 3). The present paper summarizes the status of these development activities. To demonstrate the capabilities of the analysis techniques, numerical studies were conducted with the Space Shuttle orbiter nose-gear tire. Numerical results are presented for an inflated Space Shuttle tire, and these results are compared with experimental measurements.

Notation

- $A_{ij}, B_{ij}, D_{ij}$: stiffness coefficients of two-dimensional shell model of tire ($i,j = 1,2,6$)
- $b_1, b_2$: parameters defining geometry of tire cross section (see fig. 3)
- $c_{ij}$: stiffness coefficients of individual unidirectional plies ($i,j = 1,2,4,5,$ and $6$)
- $d$: diameter of tire nylon cord
- $\{E\}$: vector of strain parameters for shell model of tire (see eq. (2))
- $E_c, E_r$: Young's moduli for nylon cord and rubber
- $\{E\}_{n}$: vector of strain parameters associated with $n$th Fourier harmonic for shell model of tire (see eq. (2) and table 1)
- $E_{To}$: elastic modulus (see tables 7 and 8 and fig. 9)
- $E_1, E_2$: elastic moduli in direction of tire cord and normal to it
- $\text{epi}$: cord end count, ends per inch
- $f_c$: volume fraction of nylon cord in individual plies of tire
- $\{f\}_{(n)}$: vector defined in equations (5)
- $G_c, G_r$: shear moduli for tire cord and rubber
\{G\}^{(n)} \text{ vector of nonlinear terms associated with } n\text{th Fourier harmonic (see eqs. (5))}

\[G_{12}, G_{13}\] \text{ shear moduli in plane of tire cord}

\[G_{23}\] \text{ shear modulus normal to plane of tire cord}

\{H\} \text{ vector of stress-resultant parameters for shell model of tire (see eq. (3))}

\{H\}_n \text{ vectors of stress-resultant parameters associated with } n\text{th Fourier harmonic for shell model of tire (see eq. (3) and table 1)}

\[h\] \text{ total thickness of tire}

\[\bar{h}\] \text{ nondimensional thickness of tire (see fig. 2)}

\[h_k\] \text{ thickness of individual layers of two-dimensional shell model}

\[h_o\] \text{ total thickness of tire at } \xi = 0 \text{ (see fig. 3)}

\[\overline{[K]}, \overline{[K]}\] \text{ matrices defined in equations (6)}

\[\overline{[K]}^{(IJ)}\] \text{ matrix containing nonlinear terms (see eqs. (9) and (11))}

\[\overline{[K]}^{(n)}\] \text{ linear matrix associated with } n\text{th Fourier harmonic (see eqs. (5))}

\[\overline{[K_o]}, [K_o]\] \text{ submatrices of } \overline{[K]}^{(n)} \text{ (see eqs. (8))}

\[\overline{[\bar{k}]} \overline{[\bar{k}]\]} \text{ matrices associated with reduced equations (see eqs. (16) and (17))}

\[l\] \text{ number of segments along tire surfaces}

\[M_s, M_\theta, M_{s\theta}\] \text{ bending and twisting stress resultants (see fig. 1 and table 1)}

\[m\] \text{ number of displacement nodes in element}

\[N\] \text{ number of Fourier harmonics which are greater than or equal to 1}

\[N^t\] \text{ shape functions used in approximating generalized displacements and external loading}

\[N^l\] \text{ shape functions used in approximating stress resultants and strain components}

\[N_s, N_\theta, N_{s\theta}\] \text{ extensional stress resultants (see fig. 1 and table 1)}

\[n\] \text{ vector normal to reference surface of tire}

\[n\] \text{ Fourier harmonic (circumferential wave number)}

\[n_o\] \text{ Fourier harmonic at which global approximation vectors are generated}

\{P\}, \{\tilde{P}\} \text{ right-side vectors in equations (13)}

\{P\}^{(n)} \text{ consistent load vector associated with } n\text{th Fourier harmonic for tire (see eqs. (5))}

\[p_n\] \text{ normal pressure components associated with } n\text{th Fourier harmonic for shell model of tire (see eq. (1))}

\[p_o\] \text{ intensity of localized normal loading of tire (see fig. 10)}

\[p_o\] \text{ inflation pressure acting normal to inner surface of tire (see figs. 3 and 4)}

\[p_s, p_\theta, p\] \text{ intensity of external loading in coordinate directions (see fig. 1)}

\[Q_s, Q_\theta\] \text{ transverse-shear stress resultants (see fig. 1 and table 1)}

\[\{q\}, \{\tilde{q}\}\] \text{ load vectors associated with reduced equations (see eqs. (18) and (19))}

\[R_1, R_2\] \text{ principal radii of curvature in meridional and circumferential directions of reference surface of shell model}

\[r\] \text{ normal distance from tire axis to reference surface (see fig. 3)}

\[r_o\] \text{ } \text{r at } \xi = 0

\[S_o, [S], [R]\] \text{ submatrices of } \overline{[K]}^{(n)} \text{ (see eqs. (8))}

\[s\] \text{ meridional coordinate of tire (see fig. 1); number of parameters used in approximating each stress resultant and strain components in element}

\[s_i\] \text{ polygonal arc lengths of segment of tire surfaces (see eq. (A2))}
In the present study we model the Space Shuttle orbiter nose-gear tire using a moderate-rotation
Sanders-Budiansky shell theory with the effects of transverse shear deformation and laminated anisotropic material response included (refs. 10 and 11). A total Lagrangian formulation is used and the fundamental unknowns consist of the five generalized displacements, the eight stress resultants, and the corresponding eight strain components of the middle surface. The sign convention for the different tire stress resultants and generalized displacements is shown in figure 1. The concepts presented in the succeeding sections can be extended to higher order shear deformation theories as well as to three-dimensional continuum theory.

Spatial Discretization of the Tire

Each of the generalized displacements, the stress resultants, and the strain components is expanded in a Fourier series of the circumferential coordinate \( \theta \). The discretization in the meridional direction is performed through the use of a three-field mixed finite-element model. The following expressions are used for approximating the external loading, strain components, stress resultants, and generalized displacements within each element:

\[
\begin{align*}
p(s, \theta) &= N^t \left( \sum_{n=0}^{\infty} p_n^t \cos n\theta + \sum_{n=1}^{\infty} \bar{p}_n^t \sin n\theta \right) \quad (1) \\
E(s, \theta) &= \overline{N}^l \left( \sum_{n=0}^{\infty} E_n^l \cos n\theta + \sum_{n=1}^{\infty} \bar{E}_n^l \sin n\theta \right) \quad (2) \\
H(s, \theta) &= \overline{N}^l \left( \sum_{n=0}^{\infty} H_n^l \cos n\theta + \sum_{n=1}^{\infty} \bar{H}_n^l \sin n\theta \right) \quad (3) \\
X(s, \theta) &= N^t \left( \sum_{n=0}^{\infty} X_n^t \cos n\theta + \sum_{n=1}^{\infty} \bar{X}_n^t \sin n\theta \right) \quad (4)
\end{align*}
\]

where \( N^t \) are the shape functions used in approximating the generalized displacements and external loading in the meridional direction; \( \overline{N}^l \) are the shape functions used in approximating the strain components and stress resultants; \( p_n^t \) and \( \bar{p}_n^t \) refer to the normal pressure coefficients; \( X_n^t \) and \( \bar{X}_n^t \) refer to the generalized displacement coefficients; \( E_n^l \) and \( \bar{E}_n^l \) refer to the strain parameters; \( H_n^l \) and \( \bar{H}_n^l \) refer to the stress-resultant parameters; and subscript \( n \) refers to the quantities associated with the Fourier harmonic \( n \). Note that the degree of the polynomial shape functions \( \overline{N}^l \) is lower than that of \( N^t \). Moreover, the continuity of the strain components and stress resultants is not imposed at the interelement boundaries and, therefore, the strain and stress-resultant parameters can be eliminated on the element level.

In equations (1) to (4), the range of \( i \) is 1 to \( m \), the number of displacement nodes in the element; the range of \( l \) is 1 to \( s \), the number of parameters used in approximating each of the strain components and stress resultants. The shell variables without a bar are the coefficients of the cosine series, the shell variables with a bar are the coefficients of the sine series, and a repeated superscript denotes summation over its entire range. Henceforth, the vectors of the 10 generalized displacement parameters, of the 16 strain parameters, and of the 16 stress-resultant parameters chosen in association with the harmonic \( n \) are denoted by \( \{X\}_n \), \( \{H\}_n \), and \( \{E\}_n \), respectively. These vectors can be decomposed into symmetric and antisymmetric sets (with respect to \( \theta = 0 \)) as shown in table 1.

Governing Equations

The governing discrete equations of the tire are obtained through application of the three-field Hu-Washizu mixed variational principle (see ref. 12). If the number of terms (harmonics) retained in the Fourier series is \( N + 1 \), then the governing equations can be written in the following compact form:

\[
\begin{align*}
\left\{ f^{(0)} \right\} &+ \int_{0}^{N+1} K^{(0)} (Z_0, Z_1, \ldots, Z_N) \\left( \begin{array}{c} Z_0 \\ Z_1 \\ \vdots \\ Z_N \end{array} \right) \right. \\
&+ \left. \int_{0}^{N+1} K^{(1)} (Z_0, Z_1, \ldots, Z_N) \\right. \\
&+ \left. \int_{0}^{N+1} K^{(N)} (Z_0, Z_1, \ldots, Z_N) \\right. \\
&+ \left. \int_{0}^{N+1} K^{(N)} (Z_0, Z_1, \ldots, Z_N) \right. \\
= 0 \quad (5)
\end{align*}
\]

where \( \{Z\}_n \) \( (n = 0, 1, \ldots, N) \) is the vector of unknowns associated with the \( n \)th harmonic and includes vectors of strain parameters \( \{E\}_n \), of stress-resultant parameters \( \{H\}_n \), and of generalized...
displacements \( \{X\}_n \); \( [K]^{(n)} \) is a linear matrix; \( \{G\}^{(n)} \) is a vector of nonlinear terms; and \( \{P\}^{(n)} \) is a consistent load vector.

The following observations can be made about the governing equations (eqs. (5)):

1. The first matrix on the left side of equations (5) is block diagonal, which is a direct consequence of the orthogonality of the trigonometric functions. The orthogonality of trigonometric functions leads to uncoupling of the equations associated with the different Fourier harmonics for the linear case. For the nonlinear case, the vector \( \{G\}^{(n)} \) couples the unknowns associated with all the harmonics. (See, for example, ref. 9.)

2. The contributions of the different Fourier harmonics and the anisotropic (nonorthotropic) material coefficients to the governing equations can be identified as follows:

   a. Fourier harmonics—The block-diagonal matrix \( [K]^{(n)} \) \((n \geq 1)\) in equations (5) is linear in the Fourier harmonic \( n \). Therefore, \( [K]^{(n)} \) can be expressed as the sum of two matrices as follows:

\[
[K]^{(n)} = [\hat{K}] + n[\tilde{K}] \tag{6}
\]

   where both \( [\hat{K}] \) and \( [\tilde{K}] \) are independent of \( n \). The nonlinear vector \( \{G\}^{(n)} \) is quadratic in \( n \).

   b. Anisotropy (nonorthotropy)—A unique feature of the mixed formulation used herein is that the anisotropic (nonorthotropic) material coefficients are included only in the linear matrix \( [K]^{(n)} \). For the linear case, these anisotropic coefficients result in the coupling between the symmetric and antisymmetric shell parameters (see ref. 13 and table 2).

3. If the vector \( \{Z\}_n \) is partitioned into subvectors of parameters of strains, stress resultants, and generalized displacements, that is,

\[
\{Z\}_n = \begin{bmatrix} E \\ H \\ X \end{bmatrix}
\tag{7}
\]

then the matrix \( [K]^{(n)} \) can be written in the following form:

\[
[K]^{(n)} = \begin{bmatrix} K_o + K_a & -R \\ -R^t & S_o + nS \\ \vdots & \vdots & \ddots & \ddots \end{bmatrix} \tag{8}
\]

where the submatrices \( [K_o] \) and \( [K_a] \) contain the contributions of the orthotropic and anisotropic (nonorthotropic) material coefficients. The explicit forms of the submatrices \( [K_o], [K_a], [S_o], [S] \), and \( [R] \) are given in references 14 and 15.

4. The nonlinear vector \( \{G\}^{(n)} \) contains bilinear terms in \( \{H\}_n \) and \( \{X\}_n \) as well as quadratic terms in \( \{X\}_n \).

**Generation of the Nonlinear Response of the Tire**

For a given external loading, the governing nonlinear equations (eqs. (5)) are solved by using the Newton-Raphson iterative technique. The recursion formulas for the \( r \)th iterative cycle are

\[
\begin{bmatrix} K_0^{(1)} \\ K_1^{(1)} \\ \vdots \\ K_N^{(1)} \end{bmatrix} + \begin{bmatrix} K_0^{(0)} & K_1^{(0)} & \vdots & K_N^{(0)} \\ K_0^{(1)} & K_1^{(1)} & \vdots & K_N^{(1)} \\ \vdots & \vdots & \ddots & \vdots \\ K_0^{(N)} & K_1^{(N)} & \cdots & K_N^{(N)} \end{bmatrix} \begin{bmatrix} \Delta Z_0^{(r)} \\ \Delta Z_1^{(r)} \\ \vdots \\ \Delta Z_N^{(r)} \end{bmatrix} = -\begin{bmatrix} f_0^{(1)} \\ f_1^{(1)} \\ \vdots \\ f_N^{(1)} \end{bmatrix} \tag{9}
\]

and

\[
\begin{bmatrix} Z_0 \\ Z_1 \\ \vdots \\ Z_N \end{bmatrix}^{(r+1)} = \begin{bmatrix} Z_0^{(r)} \\ Z_1^{(r)} \\ \vdots \\ Z_N^{(r)} \end{bmatrix} + \begin{bmatrix} \Delta Z_0^{(r)} \\ \Delta Z_1^{(r)} \\ \vdots \\ \Delta Z_N^{(r)} \end{bmatrix} \tag{10}
\]
where

\[ [K]^{(IJ)} = \frac{\partial}{\partial Z_J} (G)^{(I)} \quad (I, J = 1 \text{ to } N) \]  

(11)

For each Newton-Raphson iteration (represented by eqs. (9) and (10)), another iteration loop is performed using the preconditioned conjugate gradient (PCG) technique to account for the coupling between the different harmonics (i.e., the submatrix \([K]^{(IJ)}\)). In the inner iteration loop the following uncoupled equations are solved:

\[
\begin{align*}
\left( [K]^{(0)} + [K]^{(00)(r)} \right) \{\Delta Z\}_1^{(r)} &= -\{f\}^{(0)(r)} - \hat{\lambda} \left( [K]^{(01)} \{\Delta Z\}_1 + [K]^{(02)} \{\Delta Z\}_2 + \cdots + [K]^{(0N)} \{\Delta Z\}_N \right)^{(r)} \\
[K]^{(1)} \{\Delta Z\}_1^{(r)} &= -\{f\}^{(1)(r)} - \hat{\lambda} \left( [K]^{(10)} \{\Delta Z\}_0 + [K]^{(12)} \{\Delta Z\}_2 + \cdots + [K]^{(1N)} \{\Delta Z\}_N \right)^{(r)} \\
&\vdots \\
[K]^{(N)} \{\Delta Z\}_N^{(r)} &= -\{f\}^{(N)(r)} - \hat{\lambda} \left( [K]^{(N0)} \{\Delta Z\}_0 + [K]^{(N1)} \{\Delta Z\}_1 + \cdots \right)^{(r)}
\end{align*}
\]  

(12)

where \(\hat{\lambda}\) is a tracing parameter which identifies the coupling between the different Fourier harmonics. When \(\hat{\lambda} = 1\) equations (12) are equivalent to equations (9), and when \(\hat{\lambda} = 0\) the equations uncouple in harmonics. Note that because of the special structure of the Jacobian matrix in equations (9), only the left side associated with the zeroth harmonic needs to be updated in each iteration. An efficient technique is described in the next subsection for solving equations (12).

**Efficient Generation of the Response Associated With Different Harmonics**

An efficient procedure is presented herein for generating the tire responses associated with different harmonics (solution of eqs. (12)). The basic idea of this procedure is to approximate the tire response associated with the range of Fourier harmonics, \(1 \leq n \leq N\), by a linear combination of a few global approximation vectors that are generated at a particular value of the Fourier harmonic within that range. The full equations of the finite-element model are solved for only a single Fourier harmonic, and the responses corresponding to the other Fourier harmonics are generated using a reduced system of equations with considerably fewer degrees of freedom. The proposed procedure can be conveniently divided into two phases: (1) restructuring equations (12), for \(1 \leq n \leq N\), to delineate the dependence on the Fourier harmonic \(n\), and (2) generating global approximation vectors (or modes) to approximate the response associated with a range of values of the Fourier harmonic and determining the amplitudes of the modes. Application of the procedure to stress and vibration problems of anisotropic shells of revolution is described in references 16 and 17. Its application to the solution of equations (12) is outlined subsequently.

**Restructuring of the governing equations.**

If equations (6) and (8) are used, the governing equations for the harmonic \(n\) \((1 \leq n \leq N)\) can be embedded in a single-parameter family of equations and written in the following compact form:

\[
\left( [K] + n [\tilde{K}] \right) \{\Delta Z\}_n = \{P(n)\} + \tilde{\lambda} \{\tilde{P}(n)\}
\]  

(13)

The two vectors \(\{P(n)\}\) and \(\{\tilde{P}(n)\}\) are quadratic in \(n\).

**Basis reduction and reduced system of equations.** The basis reduction is achieved by approximating the vector \(\{\Delta Z\}_n\), for a certain range of Fourier harmonics, \(1 \leq n \leq N\), by a linear combination of a few global approximation vectors which are generated at a particular value of the Fourier harmonic within that range. The approximation is expressed by the following transformation:

\[
\{\Delta Z\}_n = [\Gamma]\{\Psi\}_n
\]  

(14)
where $[\Gamma]$ is a transformation matrix whose columns are the preselected approximation vectors, and $\{\Psi\}_n$ is a vector of unknown parameters representing the amplitudes of the global approximation vectors for the harmonics $n$. The number of components of $\{\Psi\}_n$ is much less than the number of components of $\{\Delta Z\}_n$.

A Bubnov-Galerkin technique is now used to replace the original equations (eqs. (13)) by the following reduced equations in $\{\Psi\}_n$:

$$\left([\hat{K}] + n[\hat{k}]\right)\{\Psi\}_n = \{q\} + \lambda\{\hat{q}\} \quad (15)$$

where

$$[\hat{k}] = \Gamma'[\hat{K}][\Gamma] \quad (16)$$

$$[\hat{k}] = \Gamma'[\hat{K}][\Gamma] \quad (17)$$

$$\{q\} = \Gamma'\{P(n)\} \quad (18)$$

$$\{q\} = \Gamma'\{\hat{P}(n)\} \quad (19)$$

**Selection and generation of global approximation vectors.** The global approximation vectors are selected to be the response associated with a single Fourier harmonic $n_0$ and its various-order derivatives with respect to $n$. Henceforth, the derivatives of the response with respect to $n$ are referred to as “path derivatives.” The matrix $[\Gamma]$ in equations (14) is therefore given by

$$[\Gamma] = \left[\{\Delta Z\} \; \frac{\partial}{\partial n} \{\Delta Z\} \; \frac{\partial^2}{\partial n^2} \{\Delta Z\} \; \cdots \right]_{n_0} \quad (20)$$

The path derivatives are obtained by successive differentiation of the governing equations (eqs. (13)). The recursion relations for the first three global approximation vectors can be written in the following form:

$$\left([\hat{K}] + n_0[\hat{k}]\right)\{\Delta Z\}_{n_0} = \{P\} + \lambda\{\hat{P}\} \quad (21)$$

$$\left([\hat{K}] + n_0[\hat{k}]\right)\frac{\partial}{\partial n} \{\Delta Z\}_{n_0} = \frac{\partial}{\partial n} \{P\} + \lambda\frac{\partial}{\partial n} \{\hat{P}\}$$

$$- [\hat{k}][\Delta Z]_{n_0} \quad (22)$$

$$\left([\hat{K}] + n_0[\hat{k}]\right)\frac{\partial^2}{\partial n^2} \{\Delta Z\}_{n_0} = \frac{\partial^2}{\partial n^2} \{P\} + \lambda\frac{\partial^2}{\partial n^2} \{\hat{P}\}$$

$$- 2[\hat{k}]\frac{\partial}{\partial n} \{\Delta Z\}_{n_0} \quad (23)$$

Note that the left-side matrix in equations (21) to (23) is the same, and therefore it needs to be decomposed only once in the process of generating all the global approximation vectors.

**Comments on proposed procedure.** The following comments are made concerning the foregoing procedure for generating the responses associated with different harmonics:

1. The particular choice of the global approximation vectors used herein provides a direct quantitative measure of the sensitivity of the different response quantities of the tire to the circumferential wave number (the Fourier harmonic) $n$.

2. For problems requiring large numbers of Fourier harmonics (e.g., 100 or more), the range of $n$ is divided into intervals of fewer (e.g., 7) harmonics each; the global approximation vectors and reduced equations are generated at an intermediate value of $n$ within each interval, and the responses associated with the values of $n$ within that interval are generated by the foregoing procedure. Note that higher accuracy of the reduced solutions can be obtained by marching backward as well as forward in the $n$-space with the reduced equations.

3. The foregoing procedure can be directly applied to the solution of the governing nonlinear equations (eqs. (9)). This is accomplished by using a reduction method, with the control parameter selected to be load, displacement, or arc length in the solution space and the global approximation vectors selected to be the various-order derivatives of the response quantities with respect to the control parameter (see ref. 14). The global approximation vectors are obtained by successive differentiation of the governing equations (eqs. (9)) with respect to the control parameter. The left-side matrix of those equations has the same form as that of equations (9). If the global approximation vectors are evaluated at zero value for the control parameter, the matrix $[K]^{(IJ)}$ on the left side of equations (9) vanishes and the equations uncouple in harmonics. The application of the foregoing procedure considerably reduces the computational effort in generating the global approximation vectors and greatly enhances the effectiveness of the reduction method.

4. The computational effort can be further reduced by using the procedure outlined in reference 14 to uncouple the equations associated with the symmetric and antisymmetric shell parameters (with respect to $\theta = 0$). The procedure is based on transferring the anisotropic (nonorthotropic)
Results and Discussion

Numerical studies were performed to assess the accuracy of the two-dimensional shell model tire and the effectiveness of the computational procedure described in the preceding section, for generating the response associated with different harmonics. Herein, the application of the model and the computational procedure to the Space Shuttle orbiter nose-gear tire are presented. The geometric and material characteristics of the tire are given in figures 2 and 3. The Space Shuttle orbiter nose-gear tire is a 32 × 8.8 type VII bias-ply tire with a ply rating of 16. The tire carcass is constructed of 10 lamina of nylon and rubber with an additional reinforcing ply beneath the tire tread as shown in figure 2. The tire has a three-groove tread, but the model assumes a smooth tread instead. The rated load for the tire is 15,000 lb at an inflation pressure of 320 psi.

The numerical studies were performed with three-field mixed finite-element models used for the discretization of the tire in the meridional direction. Linear interpolation functions were used to approximate each of the stress resultants and strain components, and quadratic Lagrangian interpolation functions were used to approximate each of the generalized displacements. The integrals in the governing equations were evaluated with a two-point Gauss-Legendre numerical quadrature formula. Because of the symmetry of the shell meridian and loading, only half of the tire meridian was analyzed. The finite-element models used are shown in figure 4.

Modeling of the Tire Geometry

The Space Shuttle orbiter nose-gear tire was modeled as a two-dimensional laminated shell with variable thickness and variable stiffness. The outer surface of the tire was taken to be the reference surface of the shell model. A tire was cut into sections and used to obtain accurate measurements for the cross-sectional shape of the uninflated tire. A smoothed spline under tension was used to fit a curve through the measured coordinates of the cross-sectional profile in a least-squares sense (see refs. 18 and 19). Because of symmetry, only half of the cross section was modeled. A smooth variation of the second derivative, \( \frac{d^2 z}{dz^2} \), was achieved by adjusting the standard deviations of the measured profile at the data points. For a detailed description of spline smoothing techniques, see references 19 to 21.

The spline function, with the tension factor set equal to 0.1 and slope continuity enforced at both ends of the curves, was used to generate additional points along the tire meridian. The interpolation procedure is outlined in appendix A and the resulting geometric characteristics of the tire are presented in appendix B and figure 5. The thickness of the tire carcass at the nodal points of the finite-element model was computed along the normal vector to the tire reference (outer) surface by locating the points of intersection of the normal vectors with the inner surface of the tire carcass. To facilitate these computations the tire inner surface was approximated by a set of third-degree polynomials.

Evaluation of Stiffness Coefficients of the Two-Dimensional Shell Model

The cord-rubber composite was treated as a laminated material. For the purpose of computing stiffness variations in the meridional direction, the tire model was divided into seven regions, as shown in figure 2. Thicknesses of the individual carcass plies were measured at the interfaces between the regions and are given in table 3. A linear variation was assumed for the thickness within each region. The thickness of the tire tread and sidewall covering was computed by subtracting the sum of the individual ply thicknesses from the total thickness of the carcass at each location.

The material properties of the different plies were obtained with the mechanics of material approach, which has been widely applied to rigid composites. (See refs. 22 and 23.) The elastic constants of the tire constituents used in this study are presented in table 4. It was assumed that nylon cords of two different diameters were used in the construction of the tire: \( d = 0.022 \) in. for the bottom two plies and the tread reinforcement in region I, and \( d = 0.031 \) in. for all other plies.

The cord end counts (epi) for individual plies at the region interfaces are given in table 5. A linear variation was assumed for epi within each region. The formulas for evaluating the composite elastic coefficients for each ply, from the properties of the ply constituents, are given in appendix C.

The stress-strain relations of the two-dimensional shell were obtained by first transforming the stiffnesses of each of the individual layers to the global shell coordinates (\( s \) and \( \theta \)) and then integrating these coefficients through the thickness. The cord orientations in the individual plies of each region are given in table 6. The following formula was used to determine
Case of Inflation Pressure

To assess the accuracy of the shell model of the tire, the deformations produced by uniform inflation pressure of $\bar{p}_0 = 320$ psi, acting normal to the inner surface, were calculated using the geometrically nonlinear shell theory. Twelve finite elements were used in modeling half the cross section (a total of 384 strain parameters, 384 stress-resultant parameters, and 243 nonzero generalized displacements; see fig. 4(a)). The calculated values were compared with the experimental data obtained on the Space Shuttle orbiter nose-gear tire. (See fig. 2.) The results are summarized in figures 7 to 9. Close agreement between the predicted deformations and experimental results is demonstrated in figure 7. Figures 8 and 9 show the meridional variations of the generalized displacements, stress resultants, and strain energy densities. As shown in figure 9 for the case of inflation pressure, the transverse-shear strain energy density is considerably smaller than the extensional and bending strain energy density.

Case of Localized Loading

To assess the effectiveness of the computational procedure, linear solutions were obtained for a localized normal loading on the outer surface simulating contact pressure. The normal loading (in pounds per square inch) is given by the following equations, which model experimental data obtained at Langley on the shuttle tire:

$$p = \begin{cases} \frac{-p_o \beta}{\pi} - \sum_{n=1}^{10} p_n \cos n\theta & (-0.2 < \xi < 0.2) \\ 0 & (|\xi| > 0.2) \end{cases}$$

(25)

where

$$p_n = \frac{2p_o}{n\pi} \sin n\beta$$

(26)

and $p_o$ and $\beta$ are functions of $\xi$ as shown in figure 10.

Because of the symmetry of the shell meridian and loading, only half the meridian is analyzed using 37 elements (a total of 1184 stress-resultant parameters, 1184 strain parameters, and 743 nonzero displacement degrees of freedom; see fig. 4(b)). The boundary conditions at the centerline are taken to be the symmetric or antisymmetric conditions. Typical results are presented in figures 11 and 12 and in tables 7 and 8.

The foregoing procedure was applied to this problem, and 10 global approximation vectors were evaluated at $n_o = 5$ and used to generate the tire response for $n = 1$ to 10. Accuracy of the generalized displacements obtained by the procedure with 8, 10, and 15 global approximation vectors is indicated in figures 11 and 12. Each generalized displacement in figures 11 and 12 is normalized by dividing by its maximum absolute value given in tables 7 and 8. Generalized displacements predicted by the foregoing procedure with 15 vectors are almost indistinguishable from those predicted by the direct finite-element solution.

Conclusions

A computational procedure is presented for the geometrically nonlinear analysis of aircraft tires. The Space Shuttle orbiter nose-gear tire was modeled through use of a two-dimensional laminated anisotropic shell theory with the effects of variation in material and geometric parameters included.

The governing discrete equations of the tire are obtained through application of the three-field Hu-Washizu mixed variational principle. The multilevel operator splitting is used to (1) uncouple the equations associated with different harmonics, (2) identify the effects of different Fourier harmonics, and (3) delineate the effect of anisotropic (nonorthotropic) material properties. The nonlinear governing finite-element equations of the tire are solved with the Newton-Raphson iterative procedure. An efficient procedure is presented for the solution of the resulting algebraic equations at each iteration, associated with different Fourier harmonics. The effectiveness of this procedure is demonstrated by means of a numerical example of the linear response of the Space Shuttle orbiter nose-gear tire subjected to inflation loading. The tire model is subjected to localized normal loading on the outer surface (simulating the contact pressure).

Results of the present study suggest the following conclusions relative to the two-dimensional shell model used in simulating the response of the tire and to the proposed computational procedure for generating the tire response associated with different Fourier harmonics:
1. A two-dimensional shell model with variable geometric and stiffness characteristics accurately predicts the deformation of the tire when subjected to inflation pressure.

2. Use of path derivatives (derivatives of the response with respect to the Fourier harmonic) as global approximation vectors leads to accurate solutions with a small number of vectors. Therefore, the time required to solve the reduced equations is relatively small and the total time required to generate the response for a range of 10 Fourier harmonics is little more than that required for a single Fourier harmonic.

3. Global approximation vectors provide a direct measure of the sensitivity of the different response quantities to the circumferential wave (harmonic) number. Sensitivity of the global response can also be assessed with these vectors.

4. The reduction method used in the proposed computational procedure exploits the best elements of the finite-element method and of the Bubnov-Galerkin technique, as follows:
   a. The finite-element method is used as a general approach for generating global approximation vectors. The full finite-element equations are solved only for a single Fourier harmonic.
   b. The Bubnov-Galerkin technique is used as an efficient procedure for minimizing and distributing the error throughout the structure.

5. The reduction method extends the range of applicability of the Taylor series expansion by relaxing the requirement of using small changes in the circumferential wave number.
Appendix A

Summary of the Equations for a Spline Under Tension

This appendix presents the interpolation procedure which uses a smoothed spline under tension to fit a curve through the measured coordinates of the cross-sectional profile in a least-squares sense. The cubic spline function requires that the second derivative be piecewise linear and continuous. Thus, the second derivative with the effect of tension is specified by

\[
\dddot{x}(s) = \frac{\dot{x}(s) - \sigma^2 \ddot{x}(s)}{s_{i+1} - s_i} + \frac{\ddot{x}(s_{i+1}) - \sigma^2 \dot{y}_{i+1}}{s_{i+1} - s_i} \times \frac{s - s_i}{s_{i+1} - s_i}, \quad (s_i \leq s \leq s_{i+1}) \tag{A1}
\]

where \( \mathbf{x} = [x(s), z(s)] \) is the position vector for points along the segment; \( \mathbf{y}_i = [x, z]_i \) is the corresponding data at point \( i \); a dot over a symbol refers to a derivative with respect to \( s \). The chordal length (polygonal arc length) \( s_i \) is given by

\[
s_1 = 0
\]

and

\[
s_i = s_{i-1} + [(x_{i} - x_{i-1})^2 + (z_{i} - z_{i-1})^2]^{1/2}
\]

After solving equations (A1) for \( \mathbf{x}(s) \) and replacing \( \mathbf{x}(s_i) \) with \( \mathbf{y}_i \), we obtain

\[
\mathbf{x}(s) = \left[ \frac{\ddot{x}(s_i)/\sigma^2}{\sinh \sigma(s_{i+1} - s_i)} \right] \sinh \sigma(s_{i+1} - s) + \left[ \frac{\ddot{y}_i - \ddot{x}(s_i)/\sigma^2}{s_{i+1} - s_i} \right] \frac{s_{i+1} - s}{s_{i+1} - s_i} \sinh \sigma(s_{i+1} - s_i) + \left[ \frac{\frac{\ddot{x}(s_{i+1})/\sigma^2}{\sinh \sigma(s - s_i)}}{s_{i+1} - s_i} \right] \frac{(s - s_i)}{(s_{i+1} - s_i)} \tag{A3}
\]

From differentiating equations (A3) and equating right- and left-side derivatives at \( s_i \) (for \( i = 2, 3, \ldots, l - 1 \)), we obtain a set of linear algebraic equations for \( \dddot{x}(s_i) \). With the assumption of a nonperiodic spline in which both slopes at \( s_1 \) and \( s_l \) are provided, the tridiagonal differential equation is easily solved.

Once the second derivatives at point \( i = 1, 2, \ldots, l \) are obtained, the first and second derivatives \( \dddot{x}(s) \) and \( \dddot{y}(s) \) at the interpolated points are evaluated by differentiating equations (A3) and they are used to compute the geometric parameters of the tire in appendix B.

A normalized tension factor is used to eliminate a nonlinear behavior by setting (see ref. 24)

\[
\sigma' = \frac{\sigma(s_l - s_1)}{l - 1} \tag{A4}
\]

In practice, if this factor is less than 0.001, the resulting curve is approximately a cubic spline, and if it is greater than 50, the curve is nearly piecewise linear. Note that \( s \) in equations (A1) to (A4) is not the actual arc length but the chordal length. Thus, the more data points one has from smoothing, the more accurate the arc length.
Appendix B

Geometric Characteristics of the Tire

This appendix presents the geometric characteristics derived from the application of the interpolation procedure described in appendix A. From this spline interpolation, we obtain the following information about the curve at each interpolated data point: s, x, z, \( \frac{dx}{ds} \), \( \frac{dz}{ds} \), \( \frac{d^2x}{ds^2} \), and \( \frac{d^2z}{ds^2} \). The geometric parameters of the tire are then evaluated as follows:

Normal vector:

\[
\mathbf{n} = \begin{ \{ \sin \phi \\ \cos \phi \end{ \} } = \begin{ \begin{array}{c} \frac{dz}{ds} \\ \sqrt{(dz/ds)^2 + (dz/ds)^2} \end{array} \end{array} \end{array}
\]

Curvatures:

\[
\kappa_1 = \frac{1}{R_1} = -\cos^3 \phi \left( \frac{d^2x}{dz^2} \right)
\]

\[
\kappa_2 = \frac{1}{R_2} = \frac{\cos \phi}{x}
\]

Note that \( x = r \), the normal distance from the axis to the reference surface, and \( \frac{dz}{ds} = \frac{dr}{ds} \). Also note that the normal vector is used to compute the thickness, the components of the inflation pressure acting on the inner surface of the tire, and the transformation matrix with respect to the global coordinate system, if necessary.
Appendix C

Constitutive Relations for the Two-Dimensional Laminated Shell Model

This appendix presents the formulas for evaluating the composite elastic coefficients for each ply (from the properties of the ply constituents) and the resulting shell constitutive relations. The stress-strain relations of the orthotropic and unidirectional layers are given by

\[
\begin{pmatrix}
\sigma_1 \\
\sigma_2 \\
\tau_{23} \\
\tau_{13} \\
\tau_{12}
\end{pmatrix} =
\begin{bmatrix}
c_{11} & c_{12} & \cdot & \cdot \\
c_{12} & c_{22} & \cdot & \cdot \\
\cdot & \cdot & c_{44} & \cdot \\
\cdot & \cdot & \cdot & c_{55} \\
\cdot & \cdot & \cdot & c_{66}
\end{bmatrix}
\begin{pmatrix}
\varepsilon_1 \\
\varepsilon_2 \\
\gamma_{23} \\
\gamma_{13} \\
\gamma_{12}
\end{pmatrix}
\]

where the reduced stiffnesses \( c_{ij} \) are given by

\[
c_{11} = \frac{E_1}{1 - \nu_{12}\nu_{21}} \\
c_{12} = \frac{E_1\nu_{21}}{1 - \nu_{12}\nu_{21}} \\
c_{22} = \frac{E_2}{1 - \nu_{12}\nu_{21}}
\]

The elastic constants are computed by (see ref. 22)

\[
E_1 = E_r f_c + E_r (1 - f_c)
\]
\[
\nu_{12} = \nu_c f_c + \nu_r (1 - f_c)
\]
\[
E_2 = \frac{E_r [E_c (1 + 2 f_c) + E_r (1 - f_c)]}{E_c (1 - f_c) + 2 E_r (1 + 0.5 f_c)}
\]
\[
G_{12} = G_{13} = \frac{G_r [G_c + G_r + (G_c - G_r) f_c]}{[G_c + G_r - (G_c - G_r) f_c]}
\]
\[
G_{23} = 0.6 G_{12}
\]
\[
\nu_{21} = \frac{\nu_{12} E_2}{E_1}
\]

where subscripts \( c \) and \( r \) represent the quantities of the nylon cord and the rubber, respectively, and \( f_c \) is the volume fraction of the nylon cord:

\[
f_c = \frac{\pi d^2(\text{epi})}{4h_k}
\]

where \( d \) is cord diameter, \( h_k \) is the layer thickness, and epi is the cord end count (in ends per inch).
The relationships between the stress resultants and strain measures of the tire are given by

\[
\begin{bmatrix}
N_s \\
N_\theta \\
N_{s\theta} \\
M_s \\
M_\theta \\
M_{s\theta} \\
Q_s \\
Q_\theta
\end{bmatrix} = \begin{bmatrix}
A_{11} & A_{12} & A_{16} \\
& B_{11} & B_{12} & B_{16} \\
A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\
& A_{66} & B_{16} & B_{26} & B_{66}
\end{bmatrix} \begin{bmatrix}
\varepsilon_s \\
\varepsilon_\theta \\
2\varepsilon_{s\theta} \\
\kappa_s \\
\kappa_\theta \\
2\kappa_{s\theta} \\
A_{55} & A_{54} \\
A_{44}
\end{bmatrix}
\]

where \( A_{ij}, B_{ij}, \) and \( D_{ij} (i, j = 1, 2, 6) \) are shell stiffness coefficients. The nonorthotropic (anisotropic) terms are circled and dots indicate zero terms.

Figure 1. Two-dimensional shell model of tire and sign convention for external loading, generalized displacements, and stress resultants.
Figure 2. Tire cross section and thickness variation for Space Shuttle orbiter nose-gear tire used in present study. $\tilde{h} = h/h_0$. 
$b_1 = 15.1734$ in.

$b_2 = 4.12$ in.

At (1) $s = \xi = 0$

At (2) $s = 9.76$ in. $\xi = 0.5$

$h_0 = 0.75$ in. $\xi = 0.5$

$r = b_1$

Boundary conditions:

At $\xi = 0.5$

$u = v = w = \phi_s = \phi_\theta = 0$

At $\xi = 0$

Symmetry condition:

$u = v = w = \phi_s = \phi_\theta = 0$

Antisymmetry condition:

$u = v = w = \phi_s = \phi_\theta = 0$

Figure 3. Characteristics of Space Shuttle orbiter nose-gear tire used in present study. $\bar{h} = h/h_0$. 
(a) Inflation pressure.

(b) Localized normal loading on outer surfaces.

Figure 4. Finite-element models used in present study.
Figure 5. Meridional variation of geometric parameters of two-dimensional shell model of Space Shuttle orbiter nose-gear tire. Reference surface chosen to be outer surface. $r_o = 15.1737 \text{ in.}$; $\kappa_{2,0} = 0.0659 \text{ in}^{-1}$; $\kappa_{1,0} = 0.1091 \text{ in}^{-1}$. 
(a) Stiffness coefficients associated with uncoupled (orthotropic) response.

Figure 6. Meridional variation of stiffness coefficients of two-dimensional shell model of Space Shuttle orbiter nose-gear tire. $E_{T_o} = 1160.3$ psi.
(b) Coupling (nonorthotropic) stiffness coefficients. \( \alpha = 1, 2 \).

Figure 6. Concluded.

\[ p_0 = 320 \text{ psi}. \]
Figure 8. Meridional variation of generalized displacements and stress resultants produced by inflation pressure using two-dimensional shell model of Space Shuttle orbiter nose-gear tire. $|u|_{\text{max}} = 0.1440$ in.; $|v|_{\text{max}} = 0.02365$ in.; $|w|_{\text{max}} = 0.5689$ in.; $|\phi_s|_{\text{max}} = 0.309$; $|\phi_\theta|_{\text{max}} = 6.509 \times 10^{-2}$. 
Figure 9. Meridional variation of strain energy densities produced by inflation pressure using two-dimensional shell model of Space Shuttle orbiter nose-gear tire.
Figure 10. Variation of contact pressure and contact angle in meridional direction. $p_o, \max = 445.266 \text{ psi}; \beta, \max = 0.49375 \text{ rad}.$
Figure 11. Accuracy of normal displacements $w_n$ obtained with proposed procedure using two-dimensional shell model of Space Shuttle orbiter nose-gear tire.
Figure 12. Accuracy of in-plane displacements and rotation components obtained with proposed procedure using two-dimensional shell model of Space Shuttle orbiter nose-gear tire.
A computational procedure is presented for the geometrically nonlinear analysis of aircraft tires. The Space Shuttle orbiter nose-gear tire was modeled through use of a two-dimensional laminated anisotropic shell theory with the effects of variation in material and geometric parameters included. The four key elements of the procedure are (1) semianalytic finite elements in which the shell variables are represented by Fourier series in the circumferential direction and piecewise polynomials in the meridional direction; (2) a mixed formulation with the fundamental unknowns consisting of strain parameters, stress-resultant parameters, and generalized displacements; (3) multilevel operator splitting to effect successive simplifications and to uncouple the equations associated with different Fourier harmonics; and (4) multilevel iterative procedures and reduction techniques to generate the response of the shell. Numerical results of the Space Shuttle orbiter nose-gear tire model are compared with experimental measurements of the tire subjected to inflation loading.
