INTRODUCTION

The low temperature CO oxidation catalysts that are being developed and tested at NASA-Langley are fairly unique in their ability to efficiently oxidize CO at low temperatures (~303K). The bulk of the reaction data that has been collected in our laboratory has been determined using plug flow reactors with a low mass of Pt/SnO₂/SiO₂ catalyst (~0.1g) and a modest flow rate (5 - 10 sccm). We have previously characterized the surface solely in terms of N₂ BET surface areas. These surface areas have not been that indicative of reaction rate. Indeed, some of our formulations with high BET surface area have yielded lower reaction rates than those with lower BET surface areas. As a result we have begun a program, initially described at the previous NASA/RSRE conference (1), of determining the chemisorption of the various species involved in the reaction: CO, O₂, and CO₂. Such a determination will lead to a better understanding of the mechanism and overall kinetics of the reaction.

The pulsed-reactor technique, initially described by Freel (2,3), is used to determine the amount of a particular molecule that is adsorbed on the catalyst. Since there is some reaction of CO with the surface to produce CO₂ the pulsed reactor had to be coupled with a gas chromatograph in order to distinguish between the loss of CO that is due to adsorption by the surface and the loss that is due to reaction with the surface. The experimental apparatus and the technique used to determine the number of moles adsorbed is described in the next section.

METHODS

The experimental system consists of an Shimadzu Gas Chromatograph (GC) which is equipped with a Thermal Conductivity Detector (TCD). The GC column acquired from ALLTECH® is two concentric tubes, the inner tube being filled with molecular sieve while the outer column is filled with a porapak mixture. The output from the detector is recorded on a Shimadzu CR5A integrating recorder.

The catalyst sample is contained in a stainless steel tube of 1/8" O.D. The catalyst is held between two stainless steel frits, as shown in figure 1. This tube, which is located immediately upstream of the column, is placed in a small oven which is mounted on the front of the GC. The temperature of the...
catalyst can be controlled to within 0.5°C. The flow rate through the catalyst and column is 20 sccm and is monitored by a Hastings mass flow controller. All gases were High Purity. The gas mixtures all contained 2% Ne as an internal standard. These mixtures were prepared gravimetrically by Scott. The carrier gas, high purity Helium, was obtained from Union Carbide, Linde Division.

A flow schematic of the entire system is shown in figure 2. An empty tube is located in the reactor oven in addition to the tube containing the catalyst. We can switch between this tube and the reactor tube to provide an initial calibration of the system and to monitor system conditions as the reaction progresses. With this system we are able to expose the catalyst to all of the reaction conditions that have been previously used to study the reaction. We can pretreat the catalyst using our accepted procedure of 5% CO in He at 125°C for one hour. At the end of the pretreatment we can allow the catalyst to cool under Helium flow to the desired temperature. At that time we can begin introducing 1 cc pulses of the desired gas mixture onto the catalyst surface. Since it takes approximately 8 minutes to take the complete chromatogram the pulses are separated by 8 minutes. The sample is pulsed with the gas of interest until the area of the observed peak is identical to that obtained from the bypass measurements, as shown in figure 3 or until there is no discernible change in the CO concentration.

The catalyst samples were prepared at NASA-Langley using the synthetic technique described elsewhere in this issue. The particular catalysts used in this study have the following compositions by weight percent: 1.) 5.8% Pt, 39.96% SnO₂, 54.24% SiO₂ (5%Pt/SnO₂/SiO₂); 2.) 19.5% Pt, 80.5% SnO₂ (19%Pt/SnO₂); 3.) 8.55% Pt, 8.60% Pd, 35.1% SnO₂, 47.6% SiO₂ (9%Pt, 9%Pd/SnO₂/SiO₂). A 2%Pt/SnO₂ sample was obtained from Englehard Industries. In this paper these catalysts will also be referred to as 5% Pt, 19% Pt, 9% Pt/Pd, and 2% Pt respectively.

The BET surface areas reported herein were obtained at NASA-Langley with a Quantasorb® apparatus using N₂ as the adsorbate.

RESULTS

CO ADSORPTION

The fraction of CO remaining in the gas mixture as a typical experiment progresses for both a non-pretreated and a pretreated catalyst is shown in figures 4 and 5. The changes in CO are the result of both CO adsorption and the reaction of CO with the surface to produce CO₂. In both the non-pretreated and pretreated cases the initial pulses result in a significant amount of CO₂ production, as shown in figure 6. After 400 min. (approximately 50 pulses) for the non-pretreated catalyst and 100 min. (approximately 12 pulses) for the pretreated catalyst most of the processes affecting the freestream composition have ceased and the CO concentration approaches the bypass level. The fraction of CO in the freestream does not attain the original concentration but remains below that value for times of exposure that have been
as long as 1000 min. in the case of the non-pretreated sample. CO$_2$ production is essentially finished in the pretreated sample after approximately 50 min. (approximately 6 pulses).

Figures 7 and 8 summarize the CO$_2$ production observed for all of the catalysts employed in this study. The most persistent CO$_2$ production occurred with the 19% Pt catalyst which also exhibits a sharp reduction in CO$_2$ production at 400 min. (50 pulses). After pretreatment this particular catalyst exhibited no CO$_2$ production. The other non-SiO$_2$ supported catalyst, 2% Pt, did not behave in the same manner. It continued to produce CO$_2$ after 400 min. in the non-pretreated case and it has the highest initial CO$_2$ production after pretreatment. With or without pretreating the 9%Pt/Pd catalyst is the most persistent producer of CO$_2$.

Correcting for the amount of CO$_2$ produced we can determine the amount of CO that remains chemisorbed on the surface. The total amount chemisorbed is then determined by adding the amount adsorbed per pulse until the adsorption process ceases. The point at which chemisorption ceases is taken to be when the CO freestream concentration attains a constant value. This point is determined graphically as the intersection between the curved portion of the chemisorption curve with the line extended from the level portion of the graph.

The number of moles of CO that are chemisorbed can then be used to determine the number of Pt atoms exposed on the surface assuming a particular geometry for the Pt-CO complex. The surface area occupied by these Pt atoms can then be determined using a Pt cross-sectional area of 0.0841 nm$^2$ (4). The dispersion, defined as the ratio of the number of moles of CO adsorbed to the total number of moles of metal present in the catalyst, is then calculated. The results of these calculations are summarized in Table I. The catalyst with the highest CO chemisorption surface area is the 19% Pt/SnO$_2$. Such a result is contrary to that obtained from N$_2$ BET measurements as summarized in table II.

The effect of temperature upon the surface area and the dispersion is summarized for two of the catalysts in table III. Both catalysts seem to be relatively unaffected by temperature over this temperature range. There does seem to be a slight decrease in the surface area for the 2% catalyst, although the number of experiments are too limited for the results to have much significance.

O$_2$ Adsorption

O$_2$ adsorption is not observed to occur on the non-pretreated catalysts. When the catalyst is pretreated we obtain the adsorption curve shown in figure 9. This curve is identical in shape to that observed for the CO experiment except that the freestream composition does reach its original value. In addition, CO$_2$ was not observed even though the catalyst had been exposed to CO during the pretreatment process. The O$_2$ surface area and the resultant dispersion can then be calculated and are summarized for the two catalysts studied thus far in table IV. The results in table IV are calculated with the assumption that
the following reaction occurs

$$O_2(gas) \rightarrow 2O(surface)$$

As a result each $O_2$ molecule occupies two sites on the surface.

The sample that had been given the normal pretreatment and then exposed to $O_2$ as discussed in the preceding paragraph was then used for a CO chemisorption experiment. Figure 10 shows the $CO_2$ production with this extensive history compared to the CO chemisorption studies of the same catalyst with no pretreatment. The $CO_2$ evolution is virtually the same in both cases. The chemisorption curve for both cases is shown in figure 11. The chemisorption/reaction process reaches a plateau after approximately the same number of pulses in each case. The pretreated-oxygen exposed catalyst does seem to have a higher initial activity than the sample with no pretreatment.

**CO$_2$ Adsorption**

Exposing the 1% $CO_2$ mixture to the 5% Pt non-pretreated catalyst results in apparent chemisorption as shown in figure 12. The apparent chemisorption is observed to be much larger when the catalyst is pretreated but does not exist for the 2% Pt catalyst as is also shown in figure 12. Closer examination of the chromatograms showed that, for the 5% mixture (an SiO$_2$ based catalyst), the $CO_2$ peaks had broadened, interfering with the Ne peaks used as an internal standard. As a result the amount of error in the $CO_2$ concentration calculation increased significantly. When the total mass of the catalyst is reduced this apparent chemisorption is seen to decrease significantly. The apparent chemisorption that we have observed is therefore a chromatographic effect due to the SiO$_2$ present in the catalyst. We conclude, therefore, that the catalyst samples do not chemisorb $CO_2$ from the freestream gas mixture.

**DISCUSSION**

Up to this point the numerical comparisons have been made with reference to the total mass of the catalyst. The actual catalytic material is the metal(Pt,Pd)/SnO$_2$ with the SiO$_2$ present as a source of water to enhance catalyst longevity. To more accurately compare catalysts with and without SiO$_2$ the surface area has been calculated with respect to the amount of Pt/SnO$_2$ present in the material. These calculations are summarized in table V. The surface areas of the two high metal load catalysts are now similar, indicating that the SiO$_2$ is serving primarily as a diluent and not interacting directly with the metal or the SnO$_2$. However, the ratio of the CO surface area to the BET surface area for both SiO$_2$ containing catalysts is still quite low compared to the 2% Pt catalyst. This latter result is due, most likely, to differences in synthetic technique which would appear to allow more CO to bind to the surface of the 2% Pt catalyst than to any of the other catalysts in this study.

It is apparent that there can be experimental difficulties
due to the design of the system which places the catalyst immediately upstream of the GC column. Should the catalyst contain material which is also an effective chromatographic material, such as SiO₂, peak resolution may be severely affected resulting in errors in the determination of concentration. We did not observe such an effect for either O₂ or CO but with CO₂, band broadening became readily apparent. Indeed the CO₂ peak was observed to not return to baseline, overlapping severely with the Neon peak. The extent of the broadening could be affected by reducing the amount of material that is used and by the physical nature of the catalyst. The effect was not observed in the catalyst that did not contain SiO₂. In the other non-pretreated catalyst the chromatographic effect was observed to disappear when the mass of the catalyst material was reduced. However, significant error still occurred when the SiO₂ containing catalyst underwent our standard pretreatment. The retention of CO₂ by the catalyst seems to be altered in some manner. What effect this has on catalyst activity and/or catalyst longevity is unknown at this time.

Another problem with the technique is the inability, in some of the samples, to attain the bypass value of the freestream composition after long exposure of the catalyst to the gas of interest. Since attaining the bypass value was not a problem when O₂ was the gas of interest or when CO was passed over a passive material such as SnO₂, it is thought that the non-attainment of the bypass value is due to some equilibrium process between the gas phase and the surface. A possibility would be the presence of physisorbed CO which, upon leaving the surface, creates a vacant site for gas phase adsorption. The time scale of this process could be such that the released CO is not observed on the chromatogram, possibly appearing on the wings of bands or as part of a weak broad background. Such an explanation would require that, for these sites, the adsorption process is much faster than the desorption process although desorption should be essentially finished in approximately 8 minutes, the time between pulses. Experiments are currently underway where the time between pulses is varied to evaluate whether or not such an equilibrium is of importance.

CO can chemisorb upon a surface in at least two different configurations, either linear or bridged (5). The surface area will then depend upon the geometry chosen for the chemisorbed species with the bridged configuration essentially occupying two sites with twice the coverage of the linear configuration. O₂ is assumed to dissociate upon contact with the surface resulting in two surface sites for each molecule of O₂. If we assume that dissociation is occurring then the results of the O₂ experiments count the fraction of metal atoms exposed to the surface. If it is further assumed that these same atoms provide sites for CO adsorption then a comparison of O₂ chemisorption with CO chemisorption should provide an indication of the geometry of the CO chemisorbed species. The dispersion determined for 2% Pt/SnO₂ using oxygen, 0.076, compares quite favorably to that determined using CO if the linear geometry for the metal-CO complex is assumed. In contrast, the O₂ dispersion for the 5.8% Pt/SnO₂/SiO₂
catalyst, 0.044, is in good agreement with the CO dispersion if
the bridged structure is assumed. Further work on these catalysts
is in progress to determine if these apparent geometric
differences depend on the presence of SiO₂ or upon the overall
method of synthesizing the catalyst.

The difference for all the catalyst samples in the amount
of CO chemisorbed for the pretreated and non-pretreated cases is
quite large. This difference may be due in part to the presence
of CO on the surface following pretreatment which would then
block sites for further CO adsorption. We have not been able to
observe the surface adsorbed CO spectrophotometrically with
infrared spectra taken a few minutes after the pulsing of the
sample is finished. Our preliminary interpretation is that the
adsorbed CO will desorb particularly in the amount of time that
it takes for the sample to cool from the 398 K pretreatment
temperature. In addition we have already discussed the
possibility that CO desorption is responsible for the concentration not
reaching the bypass value for CO after a significant number of
pulses. If CO is not present and blocking sites then there must
be fewer sites available for adsorption after pretreatment than
before pretreatment. An obvious conclusion is that there are
fewer Pt atoms exposed to the surface, and that they have been
covered by other atoms present in the sample. Hoflund et al (6)
have observed this phenomenon in high vacuum work where they see
the Sn atom becoming more dominant on the surface, effectively
covering most of the Pt.

The interpretations discussed above are, of course,
preliminary, with several experiments yet to be done. These
include further O₂ adsorption work, and varying the time between
the pulses to attempt to quantify whether or not desorption is
affecting our surface area measurements. In addition, H₂
adsorption measurements must be performed to determine whether or
not our conclusions about the geometry of the CO metal complex
are correct.
