ABSTRACT

The near-edge structure (XANES) of the Au L$_3$ and Cu K edges of YBa$_2$Au$_{0.3}$Cu$_{2.7}$O$_{7-5}$ has been studied. X-ray diffraction suggests that Au goes on the Cu(1) site and XANES shows that this has little effect on the oxidation state of the remaining copper. The gold L$_3$ edge develops a white line feature whose position lies between that of trivalent gold oxide (Au$_2$O$_3$) and monovalent potassium gold cyanide (KAu(CN)$_2$) and whose intensity relative to the edge step is smaller than in the two reference compounds. The L$_3$ EXAFS for Au in the superconductor resembles that of Au$_2$O$_3$. However, differences in the envelope of the Fourier filtered component for the first shell suggest that the local structure of the Au in the superconductor is not equivalent to Au$_2$O$_3$.

INTRODUCTION

Substitution of many metals in YBa$_2$Cu$_3$O$_{7-4}$ (abbreviated as 123 in the following) usually depresses the transition temperature $T_c$ and has other negative effects on the superconducting properties. Trivalent metal ions like Fe, Co, or Al replace linear chain site copper, the Cu(1) site, and depress $T_c$ more slowly than Zn and Ni which replaces copper located on the CuO$_2^{2-}$ sheets, the Cu(2) site. XANES studies indicate that transition metal substitutions on the Cu(1) site usually effect the oxidation state of the Cu(2) site and its associated oxygen, but substitution of zinc has little effect on the oxidation state.

Noble metals like gold and silver are exceptional in that considerable amounts of Ag can be put into 123 before $T_c$ begins to decrease. Au/123 junctions have a small contact resistance and show little evidence of solid state reaction. This is of obvious practical benefit in the fabrication of any device requiring a junction with a normal metal. Streitz et al. examined the microstructure of Au/123 composites and found that separate Au and 123 phases exist after heat treatment in oxygen. They also determined that a small amount of Au ($x < 3$ atomic %) went into the orthorhombic 123 phase. Hepp et al. came to a similar conclusion for YBa$_2$(Au$_x$Cu$_{1-x}$)$_3$O$_{7-6}$. We report results of an examination of the Cu K and Au L$_3$ edges for YBa$_2$(Au$_x$Cu$_{1-x}$)$_3$O$_{7-6}$. Gold substitution of 8 mole % has little effect on the oxidation state of Cu in 123. The appearance of the L$_3$ edge suggests that the oxidation state of Au is lower in the superconductor than Au$_2$O$_3$, and that Au has fewer unoccupied d-states in 123 than in the trivalent oxide. The appearance of the extended x-ray absorption fine structure (EXAFS) of the Au L$_3$ edge supports earlier findings that Au is incorporated in the lattice at this concentration.
EXPERIMENTAL

The samples used in this investigation were synthesized and characterized as previously discussed.\textsuperscript{15} For YBa\textsubscript{2}(Au\textsubscript{x}Cu\textsubscript{1-x})\textsubscript{1-x}O\textsubscript{7-?}, x-ray diffraction (XRD) and x-ray photoemission (XPS) data suggest that trivalent Au goes into the Cu(I) site. When this occurs, the a and b axes remain unchanged but the c axis expands from 11.69 to 11.75 Å. This is in accord with the well-known structural chemistry of Au (i.e., Au(III) forms square planar complexes).\textsuperscript{15}

No evidence was found for the formation of secondary phases in the XRD patterns for Au substitutions less than 10 mole %; formation of a second phase was readily detected in the XRD data when more than 10 mole % was put in 123. \(T_c\) was observed to be 89 K for an 8 mole % gold containing material and 91 K for the parent 123 material made without Au\textsubscript{2}O\textsubscript{3}. Very similar conclusions were drawn in a recent study by Cieplak et al.\textsuperscript{16}, but they were unable to produce single-phase material when substituting Au for Cu. We were only able to obtain single-phase material, as determined by XRD and microscopy when using BaO\textsubscript{2} in the synthesis of the material.\textsuperscript{15}

X-ray absorption measurements were made in the transmission mode using powdered samples dispersed on adhesive tape. Au or Cu foil absorbers were placed after the samples to run in conjunction with the samples to maintain a calibrated energy scale. The work was done at the X-IIA beamline at the Brookhaven National Synchrotron Light Source.\textsuperscript{17} The monochromator resolution is estimated to be 1.0 eV at the Cu K-edge and 1.2 eV at the Au L\textsubscript{3} edge. Samples were crushed into powder, screened through 400 mesh and dispersed onto adhesive tape.

The near-edge and EXAFS data for the Cu K and Au L\textsubscript{3} edges was analyzed using standard procedures.\textsuperscript{18} A linear background was removed from the edge before normalization. To extract the EXAFS, the atomic absorption background was approximated by a spline curve. The \(\chi(k)\) data was converted from energy space to k-space assuming an \(E_0\) for Cu of 8992 eV and 11,919 eV for Au. The Fourier transforms were computed using a Gaussian window function to obtain a quantity related to the radial distribution function around the absorbing atom.

RESULTS AND DISCUSSION

The Cu K edges for the 123 material (solid line) and the 8 mole percent Au sample (dashed line) are shown in Fig. 1. The Cu K edge is complex and several interpretations of it exist.\textsuperscript{19-23} XANES results are now available for highly oriented powders or single crystal materials using polarized x-rays and these provide more reliable data on the Cu K edge.\textsuperscript{24-27} The Cu K near-edge structure arises from dipole transitions from the Cu 1s core level to the low-lying copper valence or conduction band states with \(p\) or \(\pi\) symmetry and to transitions from the Cu 1s to continuum final states that are modified by multiple scattering (shape resonances). The transitions to bound final states are related to the electron density of states and are sensitive to changes in the chemical state of the Cu while the shape resonances are sensitive to structural modification. Heald et al.\textsuperscript{24} examined the Cu K edge from 123 powders oriented such that the x-ray polarization
accompanied by shake down transitions (4p<sup>+</sup>) and peak \( \text{"C"} \) contains contributions from the 1s to 4p<sup>π</sup> band (Cu(1) and Cu(2) sites) accompanied by shake down transitions (4p<sup>π</sup>) and peak \( \text{"C"} \) contains contributions from the 1s to 4p<sup>π</sup> band (Cu(1) and Cu(2) sites).

The feature marked \( \text{"D"} \) is identified as a shape resonance. Figure 1 shows the Cu K edges of \( \text{YBa}_2\text{Cu}_3\text{O}_{7-\delta} \) and \( \text{YBa}_2\text{Au}_{0.3}\text{Cu}_{2.7}\text{O}_{7-\delta} \) to be virtually identical. This suggests that Au substitution has little or no effect on the valence of copper on either site and that the Cu is still formally divalent.

The \( \text{Au L}_3 \) edges for \( \text{YBa}_2\text{(Au}_{0.3}\text{Cu}_{1-x})\text{O}_{7-\delta} \) Au foil, monovalent \( \text{KAu(CN)}_2 \) and trivalent \( \text{Au}_2\text{O}_3 \) are shown in figure 2. The spectra for the reference compounds and Au substituted 123 have been normalized to the edge step of the Au absorption edge. The near-edge structure of the \( \text{L}_2 \) and \( \text{L}_3 \) edges in 5d transition metal compounds is dominated by 2p<sub>1/2</sub> to 5d<sub>3/2</sub> and 2p<sub>3/2</sub> to 5d<sub>1/2</sub> transitions (white line feature). The \( \text{L}_3 \) edge also has a contribution from the 2p<sub>3/2</sub> to 5d<sub>3/2</sub> but it is much weaker than the 2p<sub>1/2</sub> to 5d<sub>3/2</sub> and
2p_{3/2} to 5d_{3/2} transitions. The intensity of this feature is thought to provide a good probe of the 5d-band occupation.\textsuperscript{12} For Au (small dashed curve), the 5d band is filled and no white line feature is observed at the L\textsubscript{3} edge. The oxidation of Au to the mono- or trivalent state creates the white line feature. We find that the white line area is a little larger for Au\textsubscript{2}O\textsubscript{3} (dot-dashed line) than KAu(CN)\textsubscript{2} (dashed line) and also find that the white line feature shifts to lower photon energy when the oxidation number increases from +1 to +3. It should be noted that the ratio of the white line areas for Au\textsubscript{2}O\textsubscript{3} and KAu(CN)\textsubscript{2} is less than the ratio of d-electron removal suggested by the valence. This means that the actual d-band occupation changes less than expected from simple electron counting. The white line area for Au in 123 (solid line) is smaller than either of the reference compounds and the white line lies at lower energy than KAu(CN)\textsubscript{2}.

From Au L\textsubscript{3} near-edge data presented for YBa\textsubscript{2}(Au_{0.1}Cu_{0.9})\textsubscript{3}O\textsubscript{7-\delta}, it is clear that the electronic structure of Au in 123 differs from that of Au in trivalent Au\textsubscript{2}O\textsubscript{3}. Hepp et al.\textsuperscript{15} made an assignment of the trivalent state for Au in the 123 material using XPS measurements of the Au 4f core level. We believe the L\textsubscript{3} near-edge data shows that oxidation state of Au in the 123 material is not equivalent to that of Au in the formally trivalent oxide. Au may be "formally" trivalent in this material but significant departures in the 5d band occupation seem to be taking place. Trivalent Fe also replaces Cu on the chain site. However, substitution of the same amount of Fe depresses T\textsubscript{c} by 55 K\textsuperscript{33} rather than the 2 K found for Au. Yang et al.\textsuperscript{6} found that the Fe substitution modifies the O K edge and reduces the number of 2p holes on the oxygen. We speculate that the reduction in the apparent number of unoccupied Au 5d states for Au in 123 when compared to Au in Au\textsubscript{2}O\textsubscript{3} and the small Au induced change in T\textsubscript{c} implies that little or no change occurs in the number of the oxygen 2p holes. This is supported by our data for the Cu K edge which shows no change in the Cu-O bonding like that observed when the high T\textsubscript{c} material becomes oxygen deficient and holes are removed from the copper and oxygen.\textsuperscript{20} We also speculate that the placement of holes on the oxygen nearest neighbors reduces the hybridization of Au 5d states\textsuperscript{32} and this is responsible for the smaller L\textsubscript{3} white line area for Au in 123 when compared to Au(III) oxide.

The $\chi(k)$ data extracted from the L\textsubscript{3} edge is shown in figure 3 for YBa\textsubscript{2}(Au\textsubscript{0.1}Cu\textsubscript{0.9})\textsubscript{3}O\textsubscript{7-\delta} (a), Au\textsubscript{2}O\textsubscript{3} (b), and Au (c). The data are $k^2$-weighted to enhance the amplitude of high-$k$ oscillations. The Au L\textsubscript{3} EXAFS functions for Au substituted 123 and Au\textsubscript{2}O\textsubscript{3} look similar and are very different from that obtained for Au. The reduction in the strength of the EXAFS oscillations as a function of $k$ suggests that the Au in the superconductor is coordinated by light elements like oxygen rather than a heavy element like Au.\textsuperscript{33}

The appearance of the Au L\textsubscript{3} EXAFS provides support for our interpretation of the Au L\textsubscript{3} edge discussed earlier. The reduced strength of the white line could be rationalized by assuming that the L\textsubscript{3} edge is the sum of an oxidized Au component and metallic Au. However, a significant fraction of the Au would have to be in the metallic phase to account for the XANES result. If the Au particles are so small as to preclude getting EXAFS from the Au, it is difficult to see how the gold could have the metallic electronic structure.\textsuperscript{34} Hence,
we conclude that the gold has not formed a separate metallic component as seen during the formation of 123/Au composites.

In figure 4, the Fourier transforms of the \( k^2 \)-weighted \( L_3 \) \( \chi(k) \) data for \( \text{YBa}_2(\text{Au}_{0.1}\text{Cu}_{0.9})_3\text{O}_{7.5} \) (solid line) and \( \text{Au}_2\text{O}_3 \) (dashed line) are shown. The Fourier transformed EXAFS for both \( \text{YBa}_2(\text{Au}_{0.1}\text{Cu}_{0.9})_3\text{O}_{7.5} \) and \( \text{Au}_2\text{O}_3 \) shows a peak located at a radial coordinate of 1.6 Å. This value is close to the first shell radial coordinate measured for copper by a number of groups\(^{35-37} \) and ourselves for 123 (not shown); detailed analysis of the copper EXAFS\(^{35} \) indicates a Cu-O spacing of 1.9 Å for the Cu(1)-O bond. Hepp et al.\(^{15} \) found Au substitution causes little change in the \( a \) and \( b \) lattice constants and we think the Au-O spacing is nearly equal to that of Cu-O. Detailed analysis of the Au \( L_3 \) EXAFS data is hampered by the lack of a suitable Au-O standard.\(^{38} \) To the best of our knowledge, a detailed structural study of \( \text{Au}_2\text{O}_3 \) has not been performed. We think that \( \text{Au}_2\text{O}_3 \) is highly disordered because the Fourier transformed EXAFS for \( \text{Au}_2\text{O}_3 \) shows only the single peak corresponding to the first shell. Figure 4 shows a second peak at 2.7 Å for the Au-substituted 123 material. X-ray\(^{39} \) and neutron scattering\(^{40} \) studies of the structure of \( \text{YBa}_2\text{Cu}_3\text{O}_7 \) indicate that Ba atoms are located 3.43 Å from the Cu(1) site and the next Cu(1) atom is located at 3.86 Å. Fourier transformed EXAFS
The Fourier data for the Cu K edge shows a peak between 2 and 3 Å containing contributions from a higher order shell containing Ba. 15-37

Figure 5 shows the Fourier filtered first shell contribution to EXAFS for the Au2O3 and YBa2Au0.3Cu2.707O7-δ. The first shell contribution was obtained by back-transforming the region marked by vertical lines in figure 4. The χ(k) damps out rapidly for Au2O3; this can be attributed to the rapid decrease in backscattering amplitude of the oxygen nearest neighbors. 31

The static Debye-Waller term may also serve to diminish the EXAFS signal at higher k values. The χ(k) term does not decrease as rapidly for YBa2(Au0.1Cu0.9)3O7-δ, this suggests that the Au-O first shell in 123 is less disordered or has a smaller Debye-Waller factor.

SUMMARY AND CONCLUSIONS

XANES and EXAFS features support earlier studies 15 which concluded that small amounts of gold can be incorporated in YBa2Cu3O7-δ at the Cu(1) site. The gold shows significantly less 5d involvement in the Au-O bond in the superconductor than in Au2O3. This could be related to the doping of the oxygen with holes and this is similar to the change in the number of holes on the copper-oxygen component when the material is made superconducting by hole doping. Au has less effect on the superconducting properties than Fe presumably because the gold does not localize holes on itself. There are no obvious changes in the Cu K edge and we conclude that Au substitution has little or no effect on the chemical state of copper or oxygen. Our EXAFS data show that Au is coordinated by oxygen and is in a more ordered environment than Au2O3. The lack of a good Au-O standard hinders a more thorough analysis of the Au L3 EXAFS. The Cu K edge EXAFS is virtually identical to that published for YBa2Cu3O7-δ.

ACKNOWLEDGEMENTS

**Abstract**

The near-edge structure (XANES) of the Au L₃ and Cu K edges of YBa₂Au₀.₃Cu₂O₇₋₈ has been studied. X-ray diffraction suggests that Au goes on the Cu(1) site and XANES shows that this has little effect on the oxidation state of the remaining copper. The gold L₃ edge develops a white line feature whose position lies between that of trivalent gold oxide (Au₂O₃) and monovalent potassium gold cyanide (KAu(CN)₂) and whose intensity relative to the edge step is smaller than in the two reference compounds. The L₃ EXAFS for Au in the superconductor resembles that of Au₂O₃. However, differences in the envelope of the Fourier filtered component for the first shell suggest that the local structure of the Au in the superconductor is not equivalent to Au₂O₃.
