Static Internal Performance of an Axisymmetric Nozzle With Multiaxis Thrust-Vectoring Capability

George T. Carson, Jr., and Francis J. Capone
Langley Research Center
Hampton, Virginia
Summary

An investigation has been conducted in the static test facility of the Langley 16-Foot Transonic Tunnel to determine the internal performance characteristics of a multiaxis thrust-vectoring axisymmetric nozzle. Thrust vectoring for this nozzle was achieved by deflection of only the divergent section of the nozzle. The effects of nozzle power setting and divergent flap length were studied at nozzle deflection angles of 0° to 30° at nozzle pressure ratios up to 8.0.

The results of this investigation indicated that vectoring of the exhaust flow was achieved with essentially no turning losses. Resultant pitch vector angles greater than the geometric pitch vector angle occurred at nozzle pressure ratios for which flow separation was not present in the nozzle. The nozzle with the longer divergent flaps had higher resultant thrust performance during vectored operation and had higher turning angles at afterburner power settings.

Introduction

The mission requirements for the next generation of aircraft may dictate a highly versatile vehicle capable of supersonic cruise, short takeoffs and landings, and maneuverability at high angles of attack. Several studies have shown that significant advantages in air combat are gained with the ability to perform transient maneuvers at high angles of attack, including brief excursions into post-stall conditions (refs. 1 to 3). However, the angle-of-attack envelope of advanced fighters can be limited because of degraded stability characteristics and inadequate aerodynamic control power at high angles of attack. Providing controls that maintain high levels of effectiveness will allow future fighters to exploit a much-expanded angle-of-attack envelope.

One promising method to provide large control moments not dependent upon angle of attack is vectoring the exhaust flow. A number of investigations, conducted both at static conditions (wind off) and at forward speeds, have verified the capability of multifunction nozzles to provide pitch and yaw thrust vectoring (refs. 4 to 8). In general, most of these studies have been concerned with nonaxisymmetric nozzles. Multiaxis thrust vectoring capability for axisymmetric nozzles has been achieved through the use of post-exit vanes (ref. 9) or a gimbaled device (ref. 10). However, large weight penalties can occur with the use of both post-exit vanes and gimbaled devices. An alternate nozzle design, in which thrust vectoring is achieved by deflection of the divergent section of the nozzle, has been tested. This concept permits divergent flap vectoring through the use of synchronizing rings and actuators and by universal joint attachments at the throat.

The purpose of this investigation was to determine the internal performance characteristics of this multiaxis thrust-vectoring axisymmetric nozzle. Fixed-geometry nozzles, representing both dry and maximum afterburning power settings, were tested with two divergent flap lengths. Internal static pressures were also measured. This investigation was conducted in the static test facility of the Langley 16-Foot Transonic Tunnel.

Symbols

All forces and moments (with the exception of resultant gross thrust) are referred to the model centerline (body axis). The model (balance) moment reference center was located at station 29.39. A discussion of the data reduction procedure and definitions of the force and moment terms and the propulsion relationships used herein can be found in reference 11.

**Apparatus and Procedure**

**Static Test Facility**

This investigation was conducted in the static test facility of the Langley 16-Foot Transonic Tunnel. The test apparatus is installed in a room with a high ceiling. The jet exhausts to atmosphere through a ceiling vent aft of the nozzle test apparatus. The control room is remotely located from the test area, and a closed-circuit television camera is used to observe the model. This facility uses the same clean, dry air supply as the 16-Foot Transonic Tunnel and uses a similar air-control system—including valving, filters, and a heat exchanger (to operate the jet flow at constant stagnation temperature).

**Single-Engine Propulsion Simulation System**

A sketch of the single-engine air-powered simulation system is presented in figure 1(a) with a typical nozzle configuration installed; a photograph of the test apparatus is shown in figure 1(b).

An external high-pressure air system provided a continuous flow of clean, dry air at a controlled temperature of about 540°R at the nozzles. This high-pressure air was varied up to approximately 8 atm (1 atm = 14.696 psi) and was brought through the dolly-mounted support strut by six tubes that connect to a high-pressure plenum chamber. As shown in figure 2, the air was then discharged perpendicularly into the model low-pressure plenum through eight multiholed sonic nozzles equally spaced around the high-pressure plenum. This method was designed to minimize any forces imposed by the transfer of axial momentum as the air passed from the non-metric high-pressure plenum to the metric (mounted on the force balance) low-pressure plenum. Two flexible metal bellows were used as seals and served to compensate for axial forces caused by pressurization. The air was then passed from the model low-pressure plenum through a choke plate, instrumentation section, adapter section, and test nozzle as shown in figure 1(a).

**Nozzle Design and Model**

The nozzle design concept depicted in figure 3 permits pitch and yaw vectoring of the axisymmetric nozzle through deflection of the divergent section of the nozzle. This is accomplished through the use of synchronizing rings and actuators, universal joint attachments at the nozzle throat, and a circumferentially segmented divergent nozzle flap.

The subscale models of the axisymmetric nozzle tested during this investigation are shown in figures 4 and 5. These nozzles are fixed-geometry representations of a variable-geometry nozzle at a dry (or cruise) power setting and at an afterburning power setting. The nozzle expansion ratio was 1.35 for both power settings, and the design pressure ratio was 5.01. Two divergent flap lengths were tested for each nozzle power setting. Use of the shorter flap could result in lower nozzle weight. Geometric pitch vector angles of 0°, 10°, 20°, and 30° were provided and are shown in figure 5. Photographs of the dry power nozzle with the short flap are shown in figure 6. Some limited combined pitch/yaw thrust-vectoring configurations were tested by rotating a particular nozzle 45° at the adapter/nozzle connection.

**Instrumentation**

A six-component strain-gauge balance was used to measure forces and moments on the model (figs. 1(a) and 2). Flow conditions in the nozzle were determined from eight total-pressure probes and two total-temperature probes at Sta. 37.65 in the instrumentation section aft of the choke plate (Sta. 34.11). Nozzle total pressure and temperature are determined from the average of these measurements. Weight flow of the high-pressure air supplied to the exhaust nozzle was measured by a pair of critical-flow venturis. Internal static pressure orifices
were located along the divergent section of the nozzle as shown in figure 7. All pressures were measured with individual pressure transducers.

**Data Reduction**

All data were recorded simultaneously on magnetic tape. Approximately 50 frames of data, taken at a rate of 10 frames per second, were used for each data point; average values were used in computations. Data were obtained in an ascending order of $p_{t,j}$.

The basic performance parameters used for the presentation of results were $F/F_i$, $F_N/F_i$, $F_Y/F_i$, $F_r/F_i$, $\delta_p$, $\delta_y$, and $w_p/w_i$. With the exception of resultant gross thrust $F_r$, all force data in this report are referenced to the body axis (centerline). The component internal thrust ratios, $F/F_i$, $F_N/F_i$, and $F_Y/F_i$, represent the ratio of actual nozzle thrust (along the body axis, vertical axis, and lateral axis, respectively) to ideal nozzle thrust, where ideal nozzle thrust is based on measured weight-flow rate and total pressure and temperature conditions in the instrumentation section, as defined by the equations in the symbols definitions.

The balance force measurements from which actual thrust is subsequently obtained are initially corrected for model weight tares and balance interactions. Although the bellows arrangement was designed to eliminate pressure and momentum interactions with the balance, small bellows tares on all balance components still exist. These tares result from a small pressure difference between the ends of the bellows when internal velocities are high and from small differences in the forward and aft bellows spring constants when the bellows are pressurized. As discussed in reference 4, these bellows tares were determined by testing calibration nozzles with known performance over a range of expected normal- and side-force and yawing-, pitching-, and rolling-moment loadings. The balance data were then corrected in a manner similar to that discussed in references 4 and 11. The resultant gross thrust $F_r$ used in the resultant thrust ratio $F_r/F_i$ was then determined from these corrected balance data, as were the individual component force ratios, $F/F_i$, $F_N/F_i$, and $F_Y/F_i$. Significant differences between $F_r/F_i$ and $F/F_i$ occur when exhaust flow is directed away from the axial direction. The individual force ratios are presented to allow a direct comparison of normal- and side-force magnitudes relative to axial-force values. In addition, normalized moment ratios $PM/F_i\ell$ and $YM/F_i\ell$ are also presented. Resultant thrust vector angles in the longitudinal (pitch) plane $\delta_p$ and the lateral (yaw) plane $\delta_y$ are presented for evaluating the exhaust-flow turning capability of the various thrust-vectored configurations.

The nozzle discharge coefficient $w_p/w_i$ is the ratio of measured weight flow to ideal weight flow, where ideal weight flow is based on jet total pressure $p_{t,j}$, jet total temperature $T_{t,j}$, and measured nozzle throat area. The nozzle discharge coefficient reflects the ability of a nozzle to pass weight flow and is reduced by any momentum and vena contracta losses (effective throat area less than measured throat area $A_t$).

**Presentation of Results**

The results of this investigation are presented in both tabular and plotted form. Table 1 is an index to the tabular results contained in tables 2 to 21. Static performance data are presented in tables 2 to 5 and nozzle internal pressure ratios are given in tables 6 to 21. Internal pressure distributions for selected configurations are presented in figures 8 to 11 and static performance characteristics for the nozzles are given in figures 12 to 19 as follows:

**Discussion**

**Internal Pressure Distributions**

Internal static pressure distributions are presented in figures 8 to 11 for the dry and A/B power
nozzles with the short divergent flap section at pitch vector angles of 0° and 20°. These pressure distributions are typical of the flow characteristics of the other nozzles tested (pressure data contained in tables). The static pressure distributions on the divergent flap section of the unvectored nozzles at NPR > 2.5 show a sudden pressure rise across an exhaust-flow shock, which is indicative of shock-induced separation from the wall. This occurred for both the dry power nozzle (fig. 8(a)) and the A/B power nozzle (fig. 10(a)). Similar results were obtained for these two nozzles with the long divergent flap sections.

When vectored, the nozzles have significantly different flow characteristics than the unvectored nozzles. As shown in figure 8(b), pressures along the top (ϕ = 0°) of the nozzle were much greater than those for the unvectored nozzle. Along the bottom (ϕ = 180°) of the dry power nozzle with the short divergent flap, the flow was completely separated, up to a pressure ratio of 3.50. Figure 9 indicates that this flow separation extended at least 45° around from the bottom of the nozzle. For the dry power nozzle with the long flaps, which had a smaller divergent flap expansion angle, these conditions were evident only up to NPR = 2.0. The A/B power nozzle exhibited similar flow characteristics (figs. 10 and 11).

The pressure distributions also indicate that the actual nozzle throat for the vectored nozzles is highly inclined. For δv,p = 0°, the actual throat probably coincided with the geometric throat and could have been better defined with additional pressure measurements made nearer the throat. However, for δv,p = 20°, the actual throat (p/pj,i = 0.528) occurs at x/Lf ≈ 0.7 along the top of the nozzle and at x/Lf ≈ 0.1 along the bottom at NPR = 2.0 (fig. 8(b) or 10(b)). At NPR > 3.50, the throat has moved forward along the top to x/Lf ≈ 0.5. Because of this highly inclined throat, turning of the flow is accomplished at essentially subsonic conditions, which in turn will result in little or no turning losses. Large thrust losses will result with supersonic flow turning, which occurs, for example, with post-exit vanes used for thrust vectoring (ref. 9).

**Nozzle Static Performance**

Static performance characteristics for the various nozzles showing the effects of pitch and yaw thrust vectoring are shown in figures 12 to 17. Static nozzle performance is presented as internal thrust ratio F/Fi, resultant thrust ratio Fr/Fi, resultant pitch vector angle δp, resultant yaw vector angle δy, and nozzle discharge coefficient wp/wi. Peak nozzle performance for the dry power unvectored nozzles generally occurred between nozzle pressure ratios of 5.0 to 6.0. Typically, the peak nozzle performance is obtained at the jet nozzle pressure ratio required for fully expanded flow (the design pressure ratio), which for the current nozzles was 5.01 (figs. 12(a) and 14(a)). Peak nozzle performance was not obtained for the A/B power nozzles because facility airflow capacity restricted the maximum obtainable pressure ratio.

A comparison between the unvectored and vectored nozzles shows that differences in peak or maximum obtainable nozzle performance were less than 1 percent of the internal resultant gross thrust ratio, indicating little or no losses due to flow turning. This is because the flow was turned essentially at subsonic Mach numbers as previously discussed. (See, for example, fig. 12(a) or 17(a).) All the nozzles were effective in vectoring the thrust when the nozzle pressure ratio was large enough to reduce the amount of flow separation on the bottom of the nozzle. When extensive flow separation was not present on the lower divergent flaps, thrust vector angles equal to or greater than the geometric angles were obtained. For example, this occurs for the dry power nozzle with the short flap at NPR = 4.0 (fig. 12(a)), the lowest pressure ratio for which extensive flow separation was not present (fig. 8(b)). Similarly, figure 17(a) shows that maximum pitch vector angles were achieved at NPR = 3.0 for the A/B power nozzle with the long flap, which also was the NPR for attached flow on the bottom of the nozzle. These results are similar to those obtained for two-dimensional convergent-divergent nozzles (refs. 4 and 5).

The maximum measured vector angle for each of the nozzles was generally reached below the design pressure ratio and decreased as pressure ratio was increased. This effect of thrust angularity varying with nozzle pressure ratio is common in nonaxisymmetric nozzles whenever one flap is longer than the other relative to the exhaust flow centerline (exit plane perpendicular to centerline). A similar situation exists for the axisymmetric nozzles of the present investigation, where the bottom portion of the divergent flap section extends beyond that of the top (fig. 5). This type of nozzle geometry presents expansion surfaces of unequal length for the flow to work against, such that one side of the exhaust flow is contained longer by the divergent flap while the other side of the exhaust flow is unbounded. When either the dry or the A/B power nozzles were both pitch and yaw vectored, nearly equal resultant pitch and yaw vector angles were obtained (figs. 13(a) and 16(a)).

A comparison of internal performance for the dry and A/B power nozzles with the short and long divergent flaps is made in figures 18 and 19, respectively. Figure 18 shows that the dry power nozzles with these two flap lengths had essentially the same
resultant thrust ratios for $\delta_{v,p} = 0^\circ$ and $10^\circ$. At $\delta_{v,p} = 20^\circ$ and $30^\circ$, the nozzle with the long flaps had higher thrust performance at NPR $> 3.0$, which probably resulted from lower divergence losses for these nozzles at the higher nozzle pressure ratios. The longer flap nozzle had higher resultant pitch vector angles at NPR = 2.5 to 4.0 (depending on vectored nozzle), which were the pressure ratios at which the nozzle with the shorter flap still exhibited flow separation. Similar results were obtained for the A/B power nozzle (fig. 19) except that the resultant pitch vector angles were greater for the nozzle with longer flaps over the NPR range tested.

Concluding Remarks

An investigation has been conducted at static conditions in order to determine the internal performance characteristics of a multiaxis thrust-vectoring axisymmetric nozzle. Thrust vectoring for this nozzle would be achieved by deflection of only the divergent section of the nozzle. The effects of nozzle power setting and divergent flap length were studied at nozzle deflection angles of $0^\circ$ and $30^\circ$. This investigation was conducted in the static test facility of the Langley 16-Foot Transonic Tunnel at nozzle pressure ratios up to 8.0.

The results of this investigation indicated that vectoring of the exhaust flow was achieved with essentially no turning losses. Resultant pitch vector angles greater than the geometric pitch vector angle occurred at nozzle pressure ratios for which flow separation was not present in the nozzle. The nozzles with the longer flaps had higher resultant thrust performance during vectored operation and higher turning angles at afterburning power settings.

Figure 17. Concluded.
Figure 18. Effect of nozzle flap length on performance. Dry power.
Figure 19. Effect of nozzle flap length on performance. A/B power.
An investigation has been conducted in the static test facility of the Langley 16-Foot Transonic Tunnel to determine the internal performance characteristics of a multiaxis thrust-vectoring axisymmetric nozzle. Thrust vectoring for this nozzle was achieved by deflection of only the divergent section of the nozzle. The effects of nozzle power setting and divergent flap length were studied at nozzle deflection angles of 0° to 30° at nozzle pressure ratios up to 8.0.
