Subject: Delivery of Final Report for the Research into Display Sharing for the MCC; NASA Grant Number NAG9-370; SwRI Project Number 05-2922

Dear Ms. Uljon:

Enclosed with this letter is the final report summarizing our research into Display Sharing techniques using X Windows. This report outlines, in detail, an X Windows based approach to Display Sharing. The report also describes the current Display Sharing prototype system now installed and running at both SwRI and NASA laboratories.

Steve Hugg will be contacting you to set up a date for a presentation of the report's contents. If you have any questions or concerns, please call Steve Hugg at (512) 522-2780.

Sincerely,

Melvin A. Schrader  
Director  
Data Systems Department

1.0 INTRODUCTION

This report for NASA Grant NAG9-370, "Research into Display Sharing Techniques for Distributed Computing Environments, Final Report," describes the X-based Display Sharing Solution recommended in the Interim Report dated September 13, 1989. During the project period covered by this report, SwRI performed the following activities:

- Identification and evaluation of X-based alternative architectures
- Selection of an X-based architecture for further study
- Development of the selected X-based alternative prototype
- Identification of typical and atypical displays subject to Display Sharing
- Development of profiles, based on X-protocol type, of typical and atypical X displays
- Evaluation of performance degradation and network load based on the prototype

The Display Sharing Prototype includes the base functionality for telecast and display copy requirements. Since the prototype implementation is modular and the system design provided flexibility for the Mission Control Center Upgrade (MCCU) operational consideration, the prototype implementation can be the baseline for a production display sharing implementation. To facilitate the process this report contains the following discussion:

- Theory of Operation
- System Architecture
- Using the Prototype
- Software Description
- Research Tools
- Prototype Evaluation
- Outstanding Issues
2.0 THEORY OF OPERATION

The prototype developed by SwRI is based on the concept of a dedicated central host performing the majority of the Display Sharing processing, allowing minimal impact on each individual workstation, as shown in Figure 2.0. Each workstation participating in Display Sharing hosts programs to facilitate the user's access to Display Sharing, as shown in Figure 2.1, as well as the sending and receiving of displays to and from the dedicated host machine. The dedicated host machine receives a display from a source workstation and multiplexes the display to all appropriate receiving workstations.

2.1 System Operation

At the workstation level, the fundamental component of the prototype is a custom enhancement to the X window server (see Section 3.1.1). This modification allows all X protocol received by the server from a client application to be input into the Display Sharing system, if requested. The workstation user must request all access to the Display Sharing system. No unsolicited displays are allowed.

Each display selected for distribution by a workstation operator is associated with a 'channel.' A workstation which is distributing a display is known as a Source Station. Potential receiving workstation operators may browse a 'channel guide' to select and request a display (channel) for reception. A workstation which is receiving a distributed display is known as a Receiving Station.

2.1.1 Displays, Windows, and Clients

Internally in the Display Sharing system, the primary differentiation between displays is the client id. This value may be obtained from any X resource identifier (XID) by shifting the number right by 24 bits. For example, a typical XID (in hexadecimal) is 0x600001. The client id is 6 (e.g., in most X servers, this number is incremented for each new client; at the time this client was started there were 6 clients including this one). The number in the lower nibble (1) indicates the resource number. The prototype uses the client number to index a number of data structures on the local workstation and at the dedicated host. It is possible that the value of an XID on one workstation will equal that of one on another workstation since XIDs are only meant to refer to local resources. The prototype does not take this into account when identifying displays from different clients on different workstations and will not properly handle the case of two workstations distributing displays (windows) with identical XIDs. The prototype can make such a distinction with modifications.

2.1.2 Transmitting Displays From a Workstation

When the user elects to send a display, as shown in Figure 2.2, the Local Distribution Manager (LDM, see Section 3.1.4) on the Source Station sends the request, including display identification obtained from the user, to
FIGURE 2.0 PHASE TWO DISPLAY SHARING PROTOTYPE CONFIGURATION
FIGURE 2.1 WORKSTATION CONFIGURATION
FIGURE 2.2 DATA FLOW FOR X PROTOCOL DISTRIBUTION
the Central Distribution Manager (CDM, see Section 3.2.1). The CDM mediates the request, and if approved, selects a channel to associate the display. Once the LDM has received approval for distribution the LDM notifies both the Source Station's Server Mod (see Section 3.1.1) and the Source Station's Protocol Distributor (PD, see Section 3.1.2) that this particular display is now 'wanted' for distribution.

The PD, having received notification of a new 'wanted' display for distribution, monitors a shared memory area used by all the local Display Sharing processes for communications. When X protocol from an X client, whose display is being distributed, is received by the X server modification, it is copied into that shared memory area and the PD is alerted. The PD then retrieves the X protocol from the shared memory area and sends it to the Protocol Multiplexer (PM, see Section 3.2.2).

2.1.3 Receiving Displays At a Workstation

The workstation operator may select to receive a display, as shown in Figure 2.3, from a list of channels received from the Receiving Station's LDM. The LDM sends the reception request to the CDM. The CDM mediates the request and sends the response back to the LDM for notification to the user. The CDM also requests the PM to add a new Receiving Station to the list of receivers for that particular channel.

When the PM receives X protocol from a Source Station's PD, it then sends the X protocol to every Receiving Station's PR (Protocol Receiver, PR, see Section 3.1.3) selected to receive that channel. The Receiving Station's PR then begins to receive X protocol from the PM and processes the protocol (see Section 3.1.3), and then sends the protocol to the local X server for display.

2.2 User Operation

The workstation operator has access to the Display Sharing system using a graphical user interface, accessible through a window manager selection. The user interface is driven by the local LDM, which is the initiator of all send and receive requests.

2.2.1 Retrieve Channel Guide

A retrieve channel guide request, as shown in Figure 2.4, is initiated by selecting the Retrieve Channel Guide option presented by the LDM (see Section 3.1.4). The LDM passes this request on to the CDM (see Section 2.1.1) who keeps the current channel guide. The CDM returns the current channel guide list to the LDM, who in turn presents this list to the workstation operator. The channel guide list is a list of active channels. The channels are represented by an alpha-numeric identification.
FIGURE 2.3 DATA FLOW FOR RECEPTION OF X PROTOCOL
FIGURE 2.4 RETRIEVE CHANNEL GUIDE REQUEST PATH
2.2.2 Send Display Requests

A send display request, as shown in Figure 2.5, is initiated by selecting the Distribution Authorization option presented by the LDM (see Section 3.1.4). The operator is then prompted to use the mouse pointer to indicate which display to make available for distribution. Once the selection is made the operator is then prompted to provide an alpha-numeric identification for that display. This identification is associated with the channel selected for this display by the CDM.

When this process is complete, the LDM transmits the request to the CDM (see Section 2.1.1). If the CDM approves the request to distribute, no further operator action is required.

2.2.3 Receive Display Requests

A receive display request, as shown in Figure 2.6, is initiated by selecting the Reception Authorization option presented by the LDM (see Section 3.1.4). The LDM then presents the operator with a list of channels (along with an alpha-numeric identification) available for reception. The operator may select to receive one or more channels. Once the selection has been made, the LDM notifies the local PD (see Section 3.1.2) and Server Mod (see Section 3.1.1) of the channel selected. When X protocol is received for that channel by the PR (see Section 3.1.3) it is processed and passed on to the local X server. A window is then created by the PR for the requested channel's display. Note that at this point, the placement of the window on the screen is handled by the local window manager. Once the operator has placed the window on the screen, it is drawn in the same manner as that of the original window on the Source Station.

2.2.4 Remove Channel Requests

A remove display request, as shown in Figure 2.7, is initiated by selecting the Remove Channel option presented by the LDM (see Section 3.1.4). This request is used to remove a display (channel) from distribution. The LDM prompts the operator to indicate which channel it wishes to stop distributing on. The LDM then notifies the local PD (see Section 3.1.2) and Server Mod (see Section 3.1.1) to no longer distribute the X protocol for the display which is associated with the selected channel. The LDM also notifies the CDM (see Section 3.2.1) that the display for that particular channel is no longer available. The CDM, in turn notifies the PM (see 3.2.2) and no further X protocol for that channel is distributed.

2.2.5 Remove Receiver Requests

A remove receiver request, as shown in Figure 2.8, is initiated by selecting the Remove Receiver option presented by the LDM (see Section 3.1.4). This request is used to indicate that the workstation operator no longer wishes to receive a particular channel display. The LDM prompts the operator to indicate which display (channel) to discontinue. The LDM then

notifies the CDM (see Section 3.2.1) to remove this particular Receiving Station from the list of Receiving Stations for the selected channel. The CDM also passes this notification on to the PM (see Section 3.2.2).
3.0 SYSTEM ARCHITECTURE

3.1 The Display Sharing Workstation

The Display Sharing Workstation, as shown in Figure 2.1, hosts three Display Sharing processes and a modified X Window Server. All of these processes work together to facilitate the distribution and reception of X protocol.

3.1.1 X Server Modification

The X Server encompasses two main divisions of labor, as shown in Figure 3.0 as follows:

- Operating System related functions and Graphics Hardware related functions. The Operating System functions handle all of the communications between client and server; for a Unix system, the base level is the reading and writing of a file descriptor. When a client connects to a server in a Unix system, it is given a data structure, called the Display structure. The display structure contains information about the server connection and the server. The structure also contains a file descriptor used to communicate with the server. As an X client makes graphics requests, Xlib turns the requests into X protocol packets and stores them in a buffer area, as shown in Figure 3.1. When the buffer area is full, it is 'flushed' to the server by writing the buffer to the Display connection file descriptor.

- On the server side, this X protocol is read from the X client's file descriptor and then acted upon by the Server. Any replies or error returns are written back to the X client using the same file descriptor. The current Display Sharing prototype uses a modification to the X server, as shown in Figure 3.2, such that the X protocol packet just read from an individual X client is stored for use by the Display Sharing system.

The modification to the server consisted of a single line of source code. The line, a C statement shown below, was added at a point in the server where the protocol packet is read from an X client:

```
(void)multicast(client,ptr,len);
```

Where:

- multicast; the name of a subroutine to be called with the following arguments:
  - client; the client index whose protocol was just read. This number can be obtained by shifting any XID right 20 bits.
  - ptr; a pointer to the I/O packet just read from a client.
CLIENT I/O DISPATCHING:
- MONITOR CLIENT CONNECTIONS.
- DISPATCH MOUSE AND KEYBOARD EVENTS.
- PASS GRAPHICS COMMANDS ON.

CLIENT GRAPHICS COMMAND HANDLER:
- RECEIVE CLIENT GRAPHICS COMMANDS.
- DECOMPOSE THE REQUEST.
- CALL CORRECT GRAPHICS SUB.

KEYBOARD

MOUSE

DEVICE DRIVER(S)

GRAPHICS DISPLAY

FIGURE 3.0 THE X WINDOW SERVER IN UNIX
FIGURE 3.1 X GRAPHICS REQUEST PATH
FIGURE 3.2 THE X WINDOW SERVER WITH MODIFICATION
len; - 1, if the source of the protocol was local.  
- Actual number of X protocol request bytes  
  pointed to by ptr, if the source of the  
  protocol was from the network. (len is not  
  used by the Display Sharing prototype).

SwRI defined the requirement, and Concurrent added the single line of code  
to their X server, X Graphics Control Module (Xgcm), and performed an  
incremental link, leaving one unresolved reference, namely multicast. SwRI  
provided the multicast routine. The object module multicast.o was then  
linked, by SwRI, with the load module Xgcm (with 1 unresolved reference).  
The link results in a fully linked and executable X server, XGCM.

The multicast subroutine, as shown in Figure 3.3, is called each time there  
is X protocol read by the server from any client. The first time the  
routine is called, it creates a shared memory area for use in communication  
with the Protocol Distributor (PD), Protocol Receiver (PR), and Local  
Distribution Manager (LDM). Appendix C contains a listing and explanation  
of the data members of this shared memory area. Multicast also initializes  
this shared memory area, creates some semaphores to control dual access to  
shared memory, and then continues with normal multicast processing.

The next action taken by multicast determines if the X protocol packet is  
an X request concerning a graphics context (see Xlib Programming Manual’s  
1 and 2 for detailed information on Graphics Contexts). Such a request  
results when the client makes an X graphics call such as X_ChangeGC, which  
is used to change various values in a particular graphics context. The  
graphics context contains information such as foreground and background  
color, or line style and width. The X implementation requires that  
multicast store the state information for future use by the Display Sharing  
system.

To understand this constraint consider that all X resources (i.e.,  
colormaps, fonts, windows, graphics contexts) are referenced by a unique id  
number, called an XID. This XID is used by the X server to identify the  
resource and index into the server’s local data space for state information  
concerning the resource. The graphics context, however, is handled  
slightly differently. The graphics context, or GC, contains the type of  
information which may change quite rapidly, depending on the application.  
Line style, line width, and colors are examples of these types of data. In  
order to reduce network traffic and improve efficiency, the graphics  
context state information is contained in the X client’s data space, as  
shown in Figure 3.4, as well as the server’s. This allows the X client  
(actually Xlib) to send only the members of the GC which have changed, not  
the entire GC, thereby reducing the number of bytes sent (and thus network  
traffic).

Currently, there is no standard way for one X client to retrieve state  
information for another X client’s GC, even if the XID of that GC is known.
FIGURE 3.3 MULTICAST DATA FLOW
WRITE PROTOCOL

BUFFER 0 (EMPTY)
BUFFER 1 (EMPTY)
BUFFER 2 (FULL)
BUFFER 3 (FILLING)

READ PROTOCOL

BUFFER N

FIGURE 3.4 X PROTOCOL BUFFERS
This presents a problem when a Receiving Station's PR begins to receive X protocol from a particular Source Station. The X protocol which it receives will contain XIDs, which refer to X resources on the Source Station only and are not directly translatable into resources on the Receiving Station. This means that the PR must create a resource locally which is identical to the resource on the Source Station. For a GC, this means that state information contained in the GC must be retrieved from the Source Station and transmitted to the Receiving Station. Since there is no standard programmatic method for accessing this state information external to the client which created the GC, the state information must be stored by multicast on the first X protocol transfer from the client to the server.

The storage of this state information must take place even for clients which are not currently being distributed. This is necessary to maintain the currency of the state information in case that client is distributed in the future.

Determination of whether a client is distributed is based on a set of flags in the shared memory area. These flags are implemented as an array (wanted) of integers which are used to indicate when a particular client's protocol is 'wanted' for distribution. The LDM sets and clears the values. If the X protocol received is for a client which is not currently 'wanted', multicast simply returns and takes no further action. If the X protocol received is from a client which is 'wanted' for distribution, multicast copies the client buffer into shared memory and notifies the PD that there is protocol available for distribution by unlocking the semaphore associated with that buffer. Multicast then returns and takes no further action.

### 3.1.2 Protocol Distributor

The Protocol Distributor (PD) is a separate task, responsible for routing X protocol from a distributed client (X application) to the Protocol Multiplexer (PM). When multicast places X protocol into the shared memory buffer, PD copies the protocol out of shared memory, forms a standard Display Sharing data package, and then writes the data package to the PM. The PD also responds to requests from the local Protocol Receiver (PR), indicated through shared memory area flags, to send state information concerning window attributes or graphics contexts to the PM.

#### 3.1.2.1 PD Initialization

Upon initialization, PD takes the following sequence of actions:

- Set up signal catching/handling routines for SIGALRM (used for timeout purposes) and SIGUSR1 (used by the PR to signal a state information request).
- Attach to the shared memory segment created by multicast.
- Make contact with the Central Distribution Manager (CDM) and the PM. This is done by issuing a remote procedure call (RPC).
broadcast to any existing CDM. On the basis of this broadcast, the CDM assigns the PD a unique ID number, indicating that all the necessary data structures have been set up by the CDM and the PM.

- The PD then connects to the PM by first creating a socket with the socket() system call, and then connecting and establishing a logical circuit to the PM by using the connect() system call. At this point the PD has established a logical connection path to the PM. This is the path used to transmit X protocol from the source workstation to the PM.

### 3.1.2.2 PD Processing

The following paragraphs outline the processing performed by PD.

#### 3.1.2.2.1 X Protocol Transmission

In the shared memory area created by multicast there are multiple buffers used (rotationally) to transmit X protocol between multicast and PD. Access to each buffer is controlled using a separate semaphore. The PD checks each buffer sequentially, attempting to lock the semaphore associated with each buffer, as shown in Figure 3.4, and then process the X protocol contained in the buffer. PD does not proceed to the next buffer until it has successfully locked the current buffer and processed X protocol from that buffer.

The buffer which multicast fills for PD may contain more than one X protocol request. Once PD has locked the buffer, it must parse the buffer and determine each type of X protocol request. Not all protocol requests are passed on to the PM. Some are not valid for distribution, such as X_ListFonts or X_GetImage. These types of requests require a reply from the server and do not directly affect what is seen on the screen. Only the protocol which affects the information presented on the screen, and does not require a reply from the server, is distributed. PD decides which X protocol is valid for distribution. With each distributable protocol request, PD builds a standard data package to send to the PM. This data package contains information such as the unique client number associated with the protocol, and the total number of bytes (see Section 3.1.2.3). Once the data package is built, the semaphore associated with that buffer is unlocked, and the data package is written to the file descriptor associated with the network connection to the PD.

#### 3.1.2.2.2 State Information Transmission and Shared Memory Requests

The PD may be requested, by the PR, to send state information (such as window attributes and graphics contexts) to the PM. The PR may do this by setting a request flag in shared memory and then sending a SIGUSR1 signal to the PD. Upon reception of the SIGUSR1 signal, the PD may perform one of the following (based on shared memory flags):

- Get Window Attributes: This request is made by the PR when state information concerning a window on another workstation is needed.
The PM gets the request, routes it to the proper workstation, and the PR/PD on that workstation sends out the state information. Eventually, that state information is received by the local PR and is used to create a local window. Figure 3.5 shows the path of a Get Window Attributes request and the actual state information through the Display Sharing system.

- **Get Graphics Context**: This request is made by the PR when it needs state information concerning a graphics context on another workstation. The PM gets the request, routes it to the proper workstation, and the PR/PD on that workstation sends out the state information. Eventually, that state information is received by the local PR and is used to create a local graphics context. Figure 3.6 shows the path of a Get Graphics Context request and the actual state information through the Display Sharing system.

- **Send Window Attributes**: This request is made by the PR when it has received a request from the PM to send a particular window's current window attributes. The PD copies the window attributes out of shared memory (having been placed there by the PR) and sends these attributes to the PM, who in turn routes it to the requesting PD/PR.

- **Send Graphics Context**: This request is made by the PR when it has received a request from the PM to send a particular graphics context's current state information. The PD copies the graphics context out of shared memory (having been constantly updated and replaced by multicast) and sends this information to the PM, who in turn routes it to the requesting PD/PR.

- **Send Expose Event**: This request is made by the PR when it has created a window (based on incoming X protocol) and needs to receive an update on all the windows from the distributor of that window. The request is sent on to the PM, who determines the source station for the particular window, and the PM sends the request to the PR on that workstation. The PR then causes an expose event to occur for the window being distributed. Assuming that expose events are handled properly by the client displaying the window, the result is a stream of X protocol visually describing those parts of the window that do not normally get updated (labels, borders, static data).
FIGURE 3.5 GET WINDOW ATTRIBUTES STATE INFORMATION DATA FLOW
FIGURE 3.6 GET GRAPHICS CONTEXT STATE INFORMATION DATA FLOW
3.1.2.3 Protocol Distributor I/O Packet Structure

The Protocol Distributor (PD) I/O packet is a structure with the following fields:

- **signal**: Array of unsigned characters describing the I/O request type
- **HDR**: A structure consisting of the following fields:
  - **length**: Integer containing the total length of the I/O packet
  - **client**: Integer containing the source client id
- **buffer**: Array of unsigned characters containing the X protocol packet

The above structure can also be referenced as an array of unsigned characters of the total combined length of the above listed fields.

3.1.3 Protocol Receiver

The Protocol Receiver (PR) is a separate task, responsible for routing X protocol received from the Protocol Multiplexer (PM) to the local X server. It does this by opening a standard connection to the local server with the `X_OpenDisplay` routine. This routine returns a pointer to a `Display` structure used to store information concerning this particular client and server relationship (Figure 3.7). Included in this information is a buffer which is used to hold X protocol requests from the client (in this case PR) to the server. Periodically this buffer is 'flushed' or written to the server. The server receives the request and acts upon them.

Another function of PR is to receive requests for state information from other PD/PR pairs on remote workstations. For this function, PR maintains a separate server connection. This connection is used to query the server for such state information, or in the case of an expose event, to cause a local expose event from the `X_SendEvent` call (see Section 3.1.3.2, PR Processing).

3.1.3.1 PR Initialization

Upon initialization, PR takes the following sequence of actions:

- Set up signal handling/catching routine for the SIGALRM signal. This signal is used to implement I/O timeouts.
- Open a connection, with the `X_OpenDisplay` call, to the local X server. This connection is used to retrieve state information concerning various X resources when requested by a PR/PD pair on a remote workstation.
- Attach to the shared memory segment which multicast has created.
FIGURE 3.7 PROTOCOL MULTIPLEXER DATA FLOW

READ PIPE?

YES → PROCESS NEW CHANNEL MAP

NO

READ X DATA FROM PD

YES → PROCESS X PROTOCOL

NO
Make contact with the Central Distribution Manager (CDM), and the PM. This is done by issuing an RPC broadcast to any existing CDM. On the basis of this broadcast, the CDM assigns the PR a unique ID number (the same as the local PD, see Section 3.1.2.1, PD Initialization).

The PR then connects to the PM by first creating a socket with the socket system call, and then using the listen and accept system calls to accept a connection by the PM. At this point the PM has established a logical connection path to the PR. This path is used to transmit X protocol from the PM to the target or destination workstation.

3.1.3.2 PR Processing

The following paragraphs outline the processing performed by PR.

3.1.3.2.1 X Protocol Reception

Once initialization has taken place and the PM has established a network connection to PR, PR will wait until it receives a communications packet from PM. Appendix C contains a list of the types of communications packets which are sent and received by PM, and also denotes the packets received by PR.

When an X_DATA packet is received, the following processing occurs:

1) The protocol is first checked to determine if it is the first X protocol packet from a client (indicated by a client number in the communications packet, see Section 3.1.2.3, Protocol Distributor I/O Packet Structure). When an X protocol packet is received from a 'new' client, PR creates a new connection to the local X server for this client with the X_OpenDisplay system call. This connection will later be used to transmit the X protocol to the server.

2) The X protocol packet is then decomposed to determine the type of X request being made, such as X_ChangeGC or X_ClearArea. Each protocol packet will be a request type indicating some action to be directed regarding a resource (window, gc, pixmap, font etc. - see the X Protocol Reference Manual for details of resources). For example, the X_ChangeGC request is used to change certain characteristics of a particular GC, such as foreground or background color for drawing. As well as containing the information for the foreground or background color, the packet also contains the XID of the GC to be affected.

3) All XIDs contained in the protocol packet are exchanged, or mapped, into XIDs which refer to local X resources. The XID contained in a received X_ChangeGC, for example, refers to a resource which exists only on the source workstation and has no meaning at the receiving
workstation. In the case of the \texttt{X\_ChangeGC} request, PR performs the following:

- If the XID is a 'new' XID, meaning this is the first X protocol packet for the XID received by PR, then PR must create a resource on the local workstation which is identical to that of the resource on the source workstation. In the case of the \texttt{X\_ChangeGC} request, PR must create a GC with the same characteristics as the GC on the source station to which the XID refers. PR does this through a request for state information concerning the XID. When the state information is received, PR creates an identical GC with the \texttt{X\_CreateGC} call. The source XID and the newly created destination XID are then added to a linked list for future reference.

- If the XID is not 'new,' then the XID is used to access the linked list of source and destination XIDs to retrieve the corresponding destination XID. This XID is then substituted into the X protocol packet.

The XID substitution is performed for all XIDs contained in the X protocol packet. At this point the X protocol packet contains only XIDs which refer to locally created resources.

4) The X protocol packet is then copied into the request buffer of the associated client's Display structure. When this buffer is full, it is sent (written to the Display structure's file descriptor) to the server. This is the same method used in standard Xlib functions.

\subsection{State Information Transmission and Shared Memory Requests}

The PR may receive requests, from PD/PR pairs on remote stations, for state information concerning local resources.

- \textbf{Get Window Attributes}: The PR receives this request as a result of a remote station's PD/PR pair requesting state information concerning a particular window. The request contains the XID of the window which refers to a resource on the receiving station. PR receives the request and retrieves the current window attributes using the \texttt{X\_GetWindowAttributes} call. PR then copies the window attributes into shared memory and makes a Send Window Attributes request of the local PD.

- \textbf{Get Graphics Context}: The PR receives this request as a result of a remote station's PD/PR pair requesting state information concerning a particular graphics context, or gc. The request contains the XID of the gc which refers to a resource on the receiving station. PR receives the request and makes a Send Graphics Context request of the local PD. The current graphics context state information has been maintained by the multicast routine (see Section 3.1.1, X Server Modification). After PR makes this request of the PD, the PD retrieves the GC state.
information from shared memory and sends it to the PM for ultimate routing to the requestor station.

- **Expose Event**: A PR receives this request from a remote station's PR, who has received an Expose event from the local server. This will result from initial creation of a Display Shared window, but could also result from the user on the remote station un-occluding the window, or de-iconifying the window. In all cases, the PR causes a local expose event by using the X_SendEvent call, specifying to the client to redraw the entire window.

### 3.1.3.2.3 Local Expose Event Solicitation

The PR solicits only one type of XEvent from the local server: Expose events. Periodically, PR checks for reception of this type of event. When an Expose event is received, the PR makes a Send Expose Event request of the local PD. The PD, in turn, sends this request to the PM for ultimate routing back to the source Station.

### 3.1.3.3 Protocol Receiver I/O Packet Structure

See Section 3.1.2.3, Protocol Distributor I/O Structure.

### 3.1.4 Local Distribution Manager

The Local Distribution Manager (LDM) provides a graphical user interface into the Display Sharing system. The LDM may be called up by a selection from the local window manager's menu. When selected, it presents the user with the following options:

- Retrieve TV Guide
- Distribution Authorization Request
- Reception Authorization Request
- Cancel Distribution on Channel
- Cancel Reception on Channel
- Stop Central Distribution Manager
- Quit

### 3.1.4.1 LDM Initialization

Upon initialization, LDM takes the following sequence of actions:

- Contact the Central Distribution Manager (CDM) by issuing an RPC broadcast and waiting for the response. The response includes the host name where the CDM resides.

- Attach to the shared memory area created by multicast. This allows access to the global variables and permits LDM to set and clear the 'wanted' flags.

- Create and display the user menu.
3.1.4.2 LDM Processing

The following paragraphs outline the processing performed by LDM.

3.1.4.2.1 Retrieve TV Guide

This option allows the user to request, from the CDM, the most current list of channel's and what is being distributed on each one. The LDM makes an RPC request, CDM_GET_LIST, as provided in Appendix D and Appendix E, of the CDM using the callrpc system call. The CDM responds to this request by issuing a reply containing the current TV Guide. The current TV Guide is a list of each channel, with the associated alpha-numeric identification string.

3.1.4.2.2 Distribution Authorization Request

With this option, the user may make a local display available for reception throughout the Display Sharing system. When this option is selected, the following actions take place:

- The user is prompted to 'pick' the window for distribution by moving the mouse cursor over the window to be distributed and clicking the left mouse button. LDM will then determine the window of the pointer and retrieve the XID for that window from the local server.

- LDM places the XID of the window to be distributed into the shared memory area.

- LDM prompts the user to enter an alpha-numeric identification for the distributed window. This identification will be the entry in the TV Guide for the channel on which this display is distributed.

- LDM makes an RPC request of the CDM, CDM_DISTR_REQ, as provided in Appendix D and Appendix F. This requests authorization to distribute a particular display on a channel. The CDM's reply returns the channel assigned for distribution.

- LDM sets the client and window id in shared memory, and then sets a flag to indicate to the PD that a new client/window is ready for distribution.

3.1.4.2.3 Reception Authorization Request

With this option, the user may elect to receive a display currently being distributed on a channel. When this option is selected, LDM performs the following actions:

- LDM requests from the CDM (using the CDM_GET_LIST RPC request) the most recent copy of the TV Guide and displays the guide to the user.
The user is prompted to select, using the mouse, one of the active channels to be received.

LDM makes an RPC request of the CDM, CDM_RECV_REQ, as provided in Appendix D and Appendix G. This request is for authorization to receive a particular channel.

LDM takes no further action. The local PR will immediately begin receiving X protocol for a 'new' channel.

3.1.4.2.4 Cancel Distribution on Channel

When a user no longer wishes to make a display available to the Display Sharing system, this option is selected. When this option is chosen, the LDM takes the following actions:

- Set the 'wanted' flag for the particular client in shared memory to FALSE, indicating to the local PD that this client's protocol should not be distributed.
- The LDM makes an RPC request of the CDM using CDM_REMV_CHAN, as provided in Appendix D and Appendix H. This request contains the channel number on which to halt distribution.

3.1.4.2.5 Cancel Reception on Channel

When a user no longer wishes to receive a channel, this option is selected. When this option is selected, the LDM takes the following actions:

- The LDM makes an RPC request of CDM using CDM_REMV_RECV, as provided in Appendix D and Appendix I. This causes the CDM to notify the PM to no longer distribute protocol to the local PR.
- The LDM notifies the local PR, through flags in shared memory, that no further protocol will be received for a particular channel. The PR then closes the display connection and removes the channel.

3.1.4.2.6 Stop Central Distribution Manager

When this option is selected, LDM requests CDM to stop and remove itself. The user should do this before selecting the 'quit' option on LDM.

3.1.4.2.7 Quit

When this option is selected, LDM detaches from the shared memory area and removes itself.
3.2 Dedicated Display Sharing Host

To reduce the Display Sharing workstation burden from sending and receiving shared displays, the concept of a dedicated Display Sharing host is utilized. The dedicated host's primary responsibility is to receive and retransmit X protocol between Display Sharing stations. Secondarily, the host acts as a clearing house for transmit and receive authorizations.

Hosted on the dedicated host are two Display Sharing processes, as follows:

- The Central Distribution Manager (CDM) and the Protocol Multiplexer (PM). The CDM is responsible for transmit and receive authorizations, and the PM is responsible for receiving X protocol from distributing stations and routing that protocol to receiving stations.

The CDM and PM both access the same shared memory area, as provided in Appendix B. The CDM uses a pipe between itself and PM to coordinate changes to the shared memory area. For example, when CDM needs to change the Channel Map (which is an expanded version of the TV Guide) it writes a byte to the shared pipe. PM periodically checks this pipe for input. When there is input, it pauses and lets CDM update the shared memory area and then continues.

3.2.1 Central Distribution Manager

The CDM may be thought of as the Display Sharing system's coordinator. Each PD/PR pair on each station must register with the CDM and must go through the CDM to send and receive displays. The CDM's functions are as follows:

- Distribution authorization
- Reception authorization
- TV Guide maintenance

The CDM achieves these objectives by becoming the RPC service server (see Appendix D for a description of the RPC requests that CDM processes).

3.2.1.1 CDM Initialization

Upon start-up, the CDM performs the following sequence of actions:

- Create and initialize a shared memory area for use in communication between the CDM and PM.
- Create a pipe for communication between CDM and PM.
- Spawn the Protocol Multiplexer (PM) task.
To create a User Datagram Protocol (UDP) socket, use the `socket` system call.

To register as an RPC service (server), use the `svc_register` system call.

Enter the RPC handling loop with the `svc_run` system call.

At this point, PM is awaiting connections from PD/PR pairs which register themselves as they come 'on-line.' The CDM is awaiting RPC requests from each station.

3.2.1.2 CDM Processing

The CDM awaits RPC requests from outside the dedicated host (PD/PR pairs). Below is a list of each type of RPC request:

**CDM_GET_LIST:**

This is a request from an LDM to send back the most recent TV Guide listing. The CDM uses the `svc_sendreply` call to send back an alpha-numeric string representing the current TV Guide listing.

**CDM_REG_DIST:**

This is a request from a PD to register itself as it comes 'on-line.' Registering a Distributor (PD) consists of initializing data structures in shared memory and assigning a Station id (which is used as an index into the data structures). This information is passed onto the PM as well.

**CDM_REG_RECV:**

This is a request from a PR to register itself 'on-line.' Registering a Receiver (PR) consists of initializing data structures in shared memory and assigning a Station id (the same one assigned to the PR's local PD). This information is passed onto the PM as well.

**CDM_DIST_REQ:**

This request is sent by an LDM which requests approval to begin distributing a display on a channel selected by CDM. The prototype implementation approves every distribution request, assuming that there is an empty channel to assign. The CDM then determines the first empty channel to assign, sets appropriate values in its data structures, and returns the approval and channel number to the requesting LDM. The CDM also notifies the PM of the change to the Channel Map.

**CDM_RECV_REQ:**

This request is sent by an LDM which requests approval to begin receiving a display associated with the requested channel. The prototype implementation approves every distribution request, assuming that the
maximum number of receivers per channel has not been reached. The CDM adds the station index (the number returned to the PD/PR pair when they register with the CDM) to the list of stations which are currently receiving a particular display on the requested channel. The CDM also notifies the PM of the change to the Channel Map.

**CDM_Remv Chan:**

This request is sent by an LDM which no longer wishes to distribute a display on the indicated channel. The CDM marks the shared memory data structures appropriately and notifies the PM that distribution on the indicated channel is no longer valid.

**CDM_Remv Recv:**

This request is sent by an LDM which no longer wishes to receive a display from the indicated channel. The CDM removes the station from the list of receivers for the channel and notifies the PM of the change to the Channel Map.

**CDM_Present:**

This request is used by both the PD and the PR as a broadcast request to 'find' the CDM/PM pair. The request is made by the PD or PR using the clnt_broadcast system call. The CDM responds by returning the hostname of the machine on which it resides.

**CDM_Go_Away:**

This request is sent by LDM to CDM to tell it to stop.

### 3.2.2 Protocol Multiplexer

The Protocol Multiplexer (PM) may be thought of as the I/O concentrator of the Display Sharing system. It is responsible for reading all X protocol from distributing Stations and then writing that protocol to all receiving Stations. The PM also processes all state information requests and transmittals.

The PM receives processing directions from the CDM from a shared memory area and two Unix pipes. The shared memory area (see Appendix B) is used to store the Channel Map and Station data structures (see Appendix J). These data structures contain information concerning each distributor, receiver, and Station in the Display Sharing system. These structures provide the CDM and PM the means to process X protocol. The Unix pipes are used to synchronize changes in the shared memory area between CDM and PM in lieu of a semaphore.
The PM is spawned by the CDM with the following parameters:

- **cdm_read_fd;** an integer (file descriptor) used to read information written to the pipe which the CDM uses to send information to the PM.
- **cdm_write_fd;** an integer (file descriptor) used to write information to the pipe which the CDM monitors.
- **shmid;** an integer containing the identification number of the shared memory area used between the CDM and PM.

### 3.2.2.1 PM Initialization

Upon initialization, PM performs the following sequence of tasks:

- Set up signal catching/handling routine for SIGALRM to implement and handle timeouts.
- Attach to the shared memory segment which CDM has created.
- Creates a socket with the `socket()` system call to use in accepting the first connection by the first PD/PR pair.
- Use the `bind()` system call to associate the socket just created with the PM's network address.
- Register intent to list and accept connections by using the `listen()` system call.
- Write port number to the CDM for later use.
- Use the `accept()` system call to await the first connection by a PD/PR pair who are 'registering.' Subsequent connections by PD/PR pairs are performed upon notification by the CDM using one of the Unix pipes.

### 3.2.2.2 PM Processing

The PM has two primary responsibilities during processing, as follows:

- Connecting to or accepting connections from PD/PR pairs, and
- Dispatching X protocol from distributors to receivers, as shown in Figure 3.7.

#### 3.2.2.2.1 New Connections

The CDM may signal to the PM that a PD or PR requests a connection, for the purposes of transmitting or receiving X protocol. The signal occurs by setting a flag in shared memory. This flag indicates that the PM should pause from normal processing and read the pipe for information. While the
PM is paused and awaiting notification on the pipe, the CDM updates shared memory with new values and then notifies the PM that shared memory has been updated.

The PM then determines the purpose of the interruption by examining several flags in the newly updated shared memory area. If the request is to connect to a PD, then the PM makes an accept() system call to complete the connection (passive connection). If it is a request from a PR, then the PM makes a socket() and connect() system call to complete the connection (active connection).

Regardless of the type of connection (active or passive), identifying data concerning each connected Station is placed into shared memory for use by both the CDM and PM. This information is used, for instance, to determine the source Station when a receiving Station has requested an Expose event.

3.2.2.2 Protocol Dispatching

The PM performs processing in three distinct areas while dispatching X protocol:

- Distributors Processing
- Receivers Processing
- State Information Processing

Distributors Processing: The PM is notified of a new distributor by a change in the Channel Map (made by the CDM after a CDM_DIST_AUTH request). In its processing the PM goes through the Channel Map. For each channel that is active, the Channel Map will contain a valid file descriptor (which results from a connection to the PD and is a virtual circuit between the distributing PD and the PM). If the channel is active (the Channel Map contains a valid file descriptor), the PM will attempt to read data from the file descriptor (see Appendix B). If data is available, it is handled according to the type of data it is.

Receivers Processing: When X_DATA is received on a channel, the Channel Map is checked to see if there are any receivers (PRs) for that channel. For every valid PR receiving the channel, the Channel Map will contain a valid file descriptor. This results from a connection to the PR and is a virtual circuit between the PM and the receiving PR. As X protocol is received, the PM goes through the list of receiving PRs and writes the data to each file descriptor.

State Information Processing: The PM is also a clearing house for state information requests and data (see Section 3.1.2.2, PD Processing). For example, when a Station requires state information concerning a graphics context (GC), the Station's PD sends the get_graphics_context_structure request (GCGS) to the PM. The PM receives the request and consults the Channel Map to determine to which Station (PR) to propagate the request. The PM then passes the request to the PR on that station. That Station
will then send out the requested state information (in this case the contents of the graphics context). The PM receives this information and routes it back to the requesting Station.

### 3.2.2.3 Performance and Redundancy

The current implementation of the Display Sharing prototype contains only one Protocol Multiplexer. One is an adequate number for prototype purposes, but there will certainly be an upper limit on the number of channels which a PM may handle before performance degradation occurs. Factors such as the frequency of update for each channel, and the average size of each X protocol packet for each channel will determine a practical maximum number of channels per PM. If that number is less than the maximum number of channels desired, modifications to the current prototype will allow multiple Protocol Multiplexers to reside on separate computers.
4.0 USING THE DISPLAY SHARING PROTOTYPE IN MOSL

Setting up and running the Display Sharing prototype in the Mission Operations Support Lab (MOSL) requires that the steps specified below be followed in their presented order. The user of the Display Sharing prototype is assumed to have basic knowledge of the Unix operating system.

Some Unix script files and aliases have been defined on the systems mentioned below. If other systems are used where these definitions do not exist, the equivalent commands have been included here, usually in parenthesis after the script file or alias name. For a complete listing of aliases and script files, see Appendix Q.

In the paragraphs below, "graphics head" refers to the physical display and keyboard of the specified server (indicated by the number after the colon in the name). "Window" refers to a window created by a login (rlogin) to a remote server from the local server.

Commands to be typed in by the user are in bold typeface.

4.1 Equipment

To run the Display Sharing prototype, the following hardware is needed:

- Source workstation
- Receiver workstation
- Dedicated host workstation

In the MOSL, Newton:l was used as the source workstation, Triton:0 (or Triton:1) as the receiver workstation and Stegy as the dedicated host. All workstations are Masscomp 6600 systems. In the remainder of this chapter, the server number will be omitted from the workstation names, unless it is required for clarity.

Note that the receiving station's display is also used to access the other two servers through remote login windows.

4.2 Setup

To start a Display Sharing session, begin by logging in on the Triton graphics head as user:root and type:

\[
\text{DS (or cd /user/DS)}
\]
\[
dproto
\]

Wait for the following three windows to be placed on the screen:

- Left window : source window (Newton)
- Upper right window : receiver window (Triton)
- Lower right window : dedicated host window (Stegy)
At the prompt, enter root password in the left window (Newton/source) and in the lower right window (Stegy/dedicated host).

In the absence of the dsproto script file, three xterm windows can be created and placed on the Triton screen manually. In one of the three windows rlogin to Newton, in another to Stegy. Leave the last one as an xterm window to Triton. The Figure 4.1 shows the approximate window layout as created by the dsproto script file.

![Figure 4.1 Display Sharing Window Layout](image)

While working on the Triton graphics head, type the following commands

- in the left window (Newton/source):

  ```
  mc  (or cd /user/DS/mc)
  setenv DISPLAY local:1.0
  ```

- in upper right window (Triton/receiver):

  ```
  mc  (or cd /user/DS/mc)
  setenv DISPLAY local:1.0  
  OR
  setenv DISPLAY local:0.0  (if using Triton:0 graphics head)
  ```

### 4.2.1 Removal of Ford Variant Server

**NOTE:** Do this ONLY if a Ford Variant server is currently running on the Newton (source) graphics head. If this step is needed, it must be done once a session, even if the Display Sharing prototype is stopped and restarted.
To replace the Ford Variant X file with a version of X that is compatible with Display Sharing, on the Triton graphics head, in the left window (Newton/source) type:

```
dsserv
OR
cd /etc/mcgraphics/Xll
cp gcml2.ds gcml2
mc (or cd /user/DS/mc)
```

If this step is done, be sure to restore the Ford Variant server (see Section 4.10) before ending the Display Sharing session.

When the Display Sharing modified server is compatible with the Ford Variant Server, this step will not have to be done.

4.3 Process and Shared Memory Cleanup

In order for the Display Sharing prototype to run correctly, all shared memory, semaphores, and processes created by a previous Display Sharing session must be removed first.

On the Triton graphics head, in all three windows, check that no shared memory or semaphores are left over from a previous Display Sharing run by typing in the command:

```
ipcs
```

This will give a list of shared memory and semaphores currently being used.

If any shared memory with 0xfb or 0xfa in the key field remains, remove it with:

```
ipcrm -m <id#> (replace <id#> with the actual number in the id field)
```

If any semaphores with a zero key field remain, remove them with:

```
ipcrm -s <id#> (replace <id#> with the actual number in the id field)
```

To list processes running on each server, type

```
ps -ed
```

The actual option letters may vary on different systems. To remove a process, use

```
kill <pid#> (or kill -9 <pid#>)
```

where <pid#> is the process id of the process to be removed.
On the Triton graphics head, in the left window (Newton/source) remove any of the following processes still running on Newton:

- Xgcm :1 or XGCM :1 (the number after the colon is the same as the server number)
- ../sim/cmap_newton
- ../sim/sc
- pd
- pr
- ldmg

On the Triton graphics head, in the upper right window (Triton/receiver) remove any of the following processes still running on Triton:

- pd
- pr
- ldmg
- dummy

If more than one copy of each of the following processes is running, leave one running and remove the rest of them:

- ../sim/cmap_triton
- ../sim/sc

When shutting down the Display Sharing session, remove all copies of the above processes.

Verify that all shared memory, semaphores and above mentioned processes are removed after each Display Sharing prototype run.

4.4 Startup

To start a Display Sharing prototype run begin by starting the dedicated host. On the Triton graphics head, in the lower right window (Stegy/dedicated host) type:

```
DHost  (or cd /user/DS/host)
cdm
```

Next start the source server. On the Triton graphics head, in the left window (Newton/source) type:

```
start_source
```
Go to the Newton graphics head and do the following:

- Log in
- Wait for LDM (Local Distribution Manager) menu-corner to appear and place it anywhere on the screen by clicking the left mouse button
- Start an application for Display Sharing (see Section 4.9)

Finally, start the receiver. On the Triton graphics head, in the upper right window type:

```
start_dest
```

Wait for the LDM menu-corner to appear and place it anywhere on the screen by clicking the left mouse button.

NOTE: All menu items and windows are selected by moving the mouse to place the cursor over the selected key or area, and then clicking the left mouse button. The sub-menus and received windows are placed by positioning the flashing corner with the mouse and clicking the left mouse button to drop the menu or window in place.

4.5 Distributing a Window

To make a window on the source station available to the receiver(s), do the following on the Newton graphics head:

- Select "Distribution Authorization Request" from the LDM menu
- Select window to be distributed
- Select "ok" in the LDM menu, if the selected window was correct
- Type an ASCII character string in the small sub-menu window to identify the display to be distributed

Multiple clients (applications) can be distributed by repeating the above process for each client.

4.6 Receiving a Window

To receive a window currently being distributed by a source station, do the following on the Triton graphics head:

- Select "Reception Authorization Request" from the LDM menu
- Place the new sub-menu window if the menu-corner appears
- Select the channel to receive from the sub-menu
- Select "Finished" in the sub-menu to make the sub-menu disappear

To receive more than one window, continue to select other available channels from the sub-menu before removing the sub-menu.
4.7 **Shutdown of Display Sharing**

To perform an orderly shutdown of the Display Sharing prototype at the end of a run or session, do the following in the order indicated below:

On the Triton graphics head, in the LDM menu do the following:
- Select "Cancel Reception on Channel"
- Select each channel being received in the sub-menu
- Select "Finished" in the sub-menu to make the sub-menu disappear

Next on the Newton graphics head, in the LDM menu do the following:
- Select "Cancel Distribution on Channel"
- Select all channels being distributed in the sub-menu
- Select "Finished" in the sub-menu to make the sub-menu disappear
- Select "Stop Central Distribution Manager"
- Select "Quit"

And on the Triton graphics head, in the LDM menu do the following:
- Select "Stop Central Distribution Manager"
- Select "Quit"

Finally, perform all steps in section 4.3 (process and shared memory cleanup) to remove any remaining shared memory, semaphores or processes left after the previous run. This step is especially important if the shutdown could not be performed in the orderly manner described above.

4.8 **Restarting Display Sharing**

To start another run of the Display Sharing prototype, continue from section 4.4 (Startup).

If any of the three windows on the Triton graphics head have been removed, remove all remaining rlogin windows, and continue from section 4.2 (Setup). However, skip section 4.2.1 (Removal of Ford Variant Server).

4.9 **Starting an Application**

Most applications can be used for Display Sharing. Some sample applications exist in the following directories:

```bash
/user/DS/sim:
bar_c    (color bar chart)
pie_c    (color pie chart)
bar      (black and white bar chart)
alpha    (display with alphabetic character parameters. Number and length of parameters and update rate of display can be selected from command line. For help type: alpha -h)
```
/user/DS/nasadisp:

  displ  (standard text display generated by NASA)
  disp2  (standard graphics display generated by NASA)

To run one of the above applications, on the Newton (source) graphics head, do the following:

For applications in the /user/DS/sim directory type:

  sim    (or cd /user/DS/sim)
       <name of application program>

For applications in the /user/DS/nasadisp directory type:

  nasa   (or cd /user/DS/nasadisp)
       <name of application program>

When cleaning up processes from a Display Sharing run, make sure that any applications that have been started are also terminated. Remove any processes not terminated at the end of a run.

4.10 Finishing Display Sharing Session

After finishing a Display Sharing session in the MOSL, the Ford Variant server must be restored if it had been removed when starting the session. The server is restored on Newton by typing the following commands at the Triton graphics head, in the left window (Newton/source):

  fvserv <server #>        (replace <server #> with the actual server number)

  OR
  cd /etc/mcgraphics/X11
  cp gcml2.fv gcml2
  Xgcm :<server #> &      (for Newton:1 this is Xgcm :1 &)

This should cause a server to start up on the Newton graphics head. If not, verify that any server running on Newton had first been removed. Now all the windows can be closed by logging out of each window.
5.0 DISPLAY SHARING SOFTWARE DESCRIPTION

The Display Sharing prototype software was designed to be modular. The communication routines and some of the common utility functions are shared by several of the functional modules.

5.1 Source and Destination Station Software

The source and destination station software is the same, the only exception being the server module in a receive-only station. In the example Display Sharing session in Chapter 4, one server (the destination) is left unmodified and therefore configured as a receive-only server. The modified server can act both as a source and a destination.

5.1.1 Server

The two versions of the server module use essentially the same software files. Options in the make-file determine which type of server is being compiled. For listings on the server files, see Appendix K.

5.1.1.1 Modified Server Version

In the modified server version, the following files are compiled and linked in with the partially linked X server object to form the executable modified server:

- multicast.c: server modification routine called by X server for every protocol packet received
- multix.c: X window related utility routines for the server modification

5.1.1.2 Pseudo Modified Server Version

On a receive-only station, the X server can be left unmodified. A pseudo modified server is started as a process running on the unmodified server. The pseudo modified server is used only at startup to create and initialize shared memory for communication between the PR, PD and LDM.

The Pseudo Modified Server consists of the following files:

- multicast.c: routine called by pseudo modified server to create shared memory for PR/PD/LDM communication
- multix.c: X window related utility routines for the pseudo modified server
- dummy.c: pseudo modified server routine that calls multicast once

An option when compiling the pseudo modified server causes multicast.c to return right after creating the shared memory. For compatibility with the
modified server, the routines multicast.c and multix.c are exactly the same in both versions of the server.

5.1.2 Protocol Distributor (PD)

The Protocol Distributor consists of the following files:

- pd.c : main PD routine
  - initialization
  - main loop:
    - check protocol buffer
      - if protocol to send then
        - distribute protocol
      - rotate buffer
    endif
- pdio.c : PD I/O related routines
- pdutil.c : PD utility routines
- alarm.c : set and clear alarm
- mutil.c : utility subroutines used by local and central management functions
- netwrite.c : network write routine

For listings on these files, see Appendix L. Files alarm.c, mutil.c and netwrite.c are shared by other modules.

5.1.3 Protocol Receiver (PR)

The Protocol Receiver consists of the following files:

- pr.c : main PR routine
  - initialization
  - main loop:
    - wait for protocol
    - translate protocol
    - send protocol to server
- prinit.c : PR initialization routines
- prio.c : PR I/O related routines
- prproto.c : PR Protocol handling routines
- prutil.c : PR general utility routines
- alarm.c : set and clear alarm
- mutil.c : utility subroutines used by local and central management functions
- netread.c : network read routine

For listings on these files, see Appendix M. Files alarm.c, mutil.c and netread.c are shared by other modules.
5.1.4 **Local Distribution Manager (LDM)**

The Local Distribution Manager consists of the following file:

- **ldmg.c**: LDM (graphics) routines

For a listing of this file, see Appendix N.

5.2 **Dedicated Host Software**

The dedicated host consists of a Central Distribution Manager (CDM) and a Protocol Multiplexer (PM). After creating the PM, CDM loops waiting for RPC requests. PM receives all protocol to be distributed and sends it to each station receiving on the channel that the protocol is being distributed on.

5.2.1 **Central Distribution Manager (CDM)**

The Central Distribution Manager consists of the following files:

- **cdm.c**: main CDM routine
  - initialization
  - create PM
  - main loop:
    - handle incoming RPC calls
- **cdm_rpc.c**: CDM RPC request handling code
- **mutil.c**: utility subroutines used by local and central management functions

For listings on these files, see Appendix O. File mutil.c is shared by other modules.

5.2.2 **Protocol Multiplexer (PM)**

The Protocol Multiplexer consists of the following files:

- **pm.c**: main PM routine
  - initialization
  - main loop:
    - channel map update
    - check for protocol to distribute
- **pmio.c**: PM I/O related routines
- **pmutil.c**: PM utility routines
- **alarm.c**: set and clear alarm
- **netwrite.c**: network write routine
- **netread.c**: network read routine

For listings on these files, see Appendix P. Files alarm.c, netread.c and netwrite.c are shared by other modules.
6.0 DISPLAY SHARING RESEARCH TOOLS

6.1 Protocol Profiler

A program called profile was developed to enable monitoring of X protocol requests generated by X-clients. An array in shared memory is used for each client to store the following data:

- The number of times each request has occurred, and
- The number of request bytes transmitted from that client.

The byte count used to calculate throughput includes Display Sharing overhead bytes but does not account for any other overhead added by the network.

Throughput, and a breakdown of requests for each client, are displayed once a minute or by user demand. The byte counts are accumulated in two ways:

- Over the time since the last printout (one minute or less), and
- Over the total time elapsed since the array was last cleared by the user.

The user can display the contents of the array at any time. Displaying - whether by user demand or initiated by the program - will not change any of the request counts. It will clear the contents of the one minute timer and the byte count accumulated since the previous display. The running total byte count is not affected. The user can request to clear the whole array, which in addition to clearing the request counts and byte counts, also clears both the one minute timer and the running timer.

There are two versions of the profile program enabling it to be used in two different ways:

- Stand Alone Version: to profile requests generated by a client in a Non-Display Sharing environment
- Display Sharing Version: to profile requests generated by a client while it is running in a Display Sharing environment

6.2 Stand Alone Version

This version runs on a server that has been modified specifically for this purpose. Any X client(s) running on this server will be monitored, and the requests they generate are displayed by the profiler which is also running on this server. Display Sharing overhead bytes are included in the throughput byte count.

6.3 Display Sharing Version

To monitor requests and actual throughput generated by clients during Display Sharing, the profiler monitors the shared memory area updated by
the regular modified server used for Display Sharing. In addition to being able to see X requests generated during normal operation, as in the stand-alone version, requests generated by receiver’s expose events are also monitored.

Throughput measured with this version will reflect a possible slowdown compared with the throughput measured with the stand alone version, if the Display Sharing prototype slows down the server.
7.0 PROTOTYPE EVALUATION

7.1 Workstation Performance

Two different approaches to Display Sharing were evaluated, the Modified Server Approach, and the Display Sharing Wedge Approach (see below).

To compare the performance of the two approaches, a test routine was developed. This evaluation program runs as a client on the workstation. The program sends repeated X requests, which require a response, to the server. It measures the time beginning when a request is sent by the client, and ending when the response is received from the server (round-trip-time).

The X.Sync request was selected as the X request to be sent, because it only causes the server to return a response. The client waits until a response is received before sending the next request.

Typically the client buffers several X requests, and sends them all at one time to the server. The X.Sync request is never buffered waiting for additional requests. It causes the request buffer to be flushed (sent to the server) immediately. This enables the timing of individual requests. In the evaluation program 50,000 such X.Sync requests were sent to the X window server and the elapsed time was measured and the average round-trip-time computed.

The evaluation test was run on an RTU/Unix 4 system. The workstation was a Concurrent 6600 system with two 33 MHz CPU's. All tasks were operating at normal priority and the standard mix of Unix processes were running.

7.1.1 Modified X Server Approach

In the Modified X Server Approach the Source Station uses a custom enhanced X window server (see Section 3.1.1), to which the client connects in the normal manner. A modified X window server is only needed on a Source Station, while a receive-only station uses either an unmodified server or the modified server.

The Modified X Server Approach incurs a minimal performance penalty compared to a non-modified server. The additional time is spent in calling the multicast routine (see Section 3.1.1) once for every protocol request. This routine determines whether the request is to be distributed, and if it is, copies the request into a buffer in the shared memory area before returning. No additional processing is performed to non-distributable requests by the Display Sharing software.

Using the above mentioned program to evaluate the workstation performance in the Modified X Server Approach, the average round-trip time per request between the client and the X server was found to be 11 milliseconds (0.011 seconds).
7.1.2 Display Sharing Wedge Approach

The Display Sharing Wedge Approach uses a non-modified X window server. Instead, a program 'layer,' here called Wedge, is inserted between the client and the server. The client connects to Wedge the same way it would to a regular X window server. All of the Display Sharing software used with Wedge is identical to that in the Modified X Server Approach.

In the Display Sharing Wedge Approach, the Wedge program reads every request sent by the source client and then calls the multicast routine. Then Wedge writes the request out to the server. The responses from the server are read by Wedge, and then written to the client.

The Wedge is transparent to both the source client and the server because it appears to the client as a server, and to the server as a regular client.

Compared to the Modified Server Approach, Wedge must perform an extra network write for every request that the client sends to the server, as well as for every response that the server sends back to the client. In addition to the extra processing done by Wedge, it itself is a process running under Unix and taking up system time.

Using the above mentioned program to evaluate the workstation performance in the Display Sharing Wedge Approach, the average round-trip time per request between the client and the server was found to be 60 milliseconds (0.06 seconds).

Based on the above results, it can be determined that using the Display Sharing Wedge Approach is approximately 5.5 times slower than the Modified X Server Approach.

7.2 Network Performance

The following section describes the calculated amount of data sent on the local area network (LAN) for the configuration as follows:

- 50 workstations,
- 250 parameters per display,
- 10 characters per parameter,
- Entire display updated every 2 seconds.

The parameters can best be displayed with the ImageText8 X request (see X Protocol Reference Manual 0). For this particular request, X Windows protocol adds 16 bytes of overhead to each parameter text string. An additional 0-3 bytes of padding is added to make the parameter byte length evenly divisible by 4. In the case of a 10 character parameter (one character per byte), 2 bytes of pad will be added.
The Display Sharing protocol adds 12 bytes of overhead to any X request. The total length of each packet containing one parameter is 40 bytes (16+10+2+12). Note that these and all byte counts calculated below are Transmission Control Protocol/Internet Protocol (TCP/IP) data byte counts, and do not account for bytes that will be added by Open Systems Interconnection (OSI) overhead when using Transport Protocol, class 4 (TP4).

With 250 parameters per display, the total number of bytes needed to update one screen is 250*40-10,000 bytes. If the screen is updated every 2 seconds, the network traffic between the source station and the dedicated host will be 5,000 bytes per second (Bps) or 40,000 bits per second (bps) at 8 bits/byte.

The same amount of traffic (5,000 bytes per second) will be added for every destination station receiving this display. So, in the case of 1 source station and 49 receiver stations, the total traffic is 50*5,000 = 250,000 Bps. The traffic would be the same if out of the 50 stations some were distributing and the rest were each receiving any one display.

Note that the above estimates require that the workstations, the LAN and the software can keep up with the necessary speed. In the above example the multicast routine in the Display Sharing software must be able to load the shared memory buffers at the rate of at least 5,000 Bps, and PD must be able to unload the buffers and send the data to the PM at the same rate of speed.

For the sample X window graphics display provided by NASA, the above calculations give the following results.

Each of the six sine-waves was drawn with

2 PolySeg(8) requests, and
1 PolySeg(4) request.

The number in the parenthesis indicates how many segments are drawn by each request. The number of segments that the PolySeg request draws determines the byte count of the request. Each segment adds 8 bytes to the basic 12 bytes of X overhead for this request. Display Sharing overhead adds 12 bytes per request for a total of 232 bytes for one pass of a sine-wave. Six sine-waves per display updated every 2 seconds, gives a LAN traffic of \((232*6)/2 = 696\) Bps. For 50 workstations the total traffic amounts to 34,800 Bps (assuming every station is distributing or receiving only one display).

The above method can be used to calculate the traffic generated by any size or type of display, by profiling the X requests that were used to generate them. Since the network traffic is based on the types and numbers of X requests generated by the clients, the applications can be coded in a way that most effectively reduces the LAN traffic.
Note that the above numbers are based on a stabilized system. The traffic varies from the above rates during receiver station start-up, when state information is being sent to the receiver(s) before the data can be displayed.

The actual traffic measured on the LAN depends on the ability of the software to keep up with the required speed. One area where speed and task scheduling is critical, is at the source station when the Protocol Distributor (PD) empties the protocol buffers in shared memory and sends them to PM (see Section 3.1.2.2). If PD is emptying the buffers slower than the multicast routine is filling them, the server may get delayed while waiting for an empty buffer to become available and this would cause the whole system to slow down.

Another critical area is at the receiver station where the Protocol Receiver (PR) sends the packets it has received to the server. Sending requests individually to the server without buffering will cause the system to slow down.
8.0 OUTSTANDING ISSUES

With the completion of the Display Sharing prototype, there are still some outstanding issues that must be resolved before a production system is implemented. Most of these issues are technical in nature; however, some require policy decisions at NASA.

8.1 Colormaps

In the Display Sharing prototype colors are passed from distributor to receiver by referencing an integer index into the colormap array at X Protocol level. This method can only reproduce original colors if the colormap is identical on all systems, both with respect to the color as well as to its index in the colormap. To insure this, one solution is to establish a standard colormap on all systems.

Another possible solution is to send the RGB value for each new color used. The RGB values will be requested from the source client, much in the same way as window attributes and graphics contexts are now being requested. The RGB value will then be parsed at the receiver to create a new entry in the local colormap. Parsing the color will create the closest matching color available on the receiving system. It will not necessarily be the identical color if the number of bit planes on the receiver were fewer than on the source. Additional processing will be required at the receiver every time a color is referenced to translate the remote index to the local one.

8.2 Fonts

The handling of different fonts is not implemented in the Display Sharing prototype. The issue of fonts is similar to the issue of colormaps, except that a font cannot be parsed by the receiver if it does not already exist. All systems need to agree on a standard set of fonts to be used by Display Sharing applications.

A default font of the correct size could be assigned if an exact matching font is not required.

8.3 Expose Events

Expose events are sent to applications to inform them that a portion of the window or all of the window needs to be regenerated. The application itself is responsible for redrawing the information in the exposed area. To simplify the problem of redrawing only the exact part that was exposed, many applications redraw the entire window when any part is exposed. Expose events are especially important to redraw static data, such as labels, which do not get updated after they are drawn, or data that is only updated very seldom.

In the Display Sharing prototype the receiver causes an expose event on the source station when a new window is created. The source then sends all the
protocol necessary to draw the initial state of the window. The application must handle expose events correctly in order for the received window to be identical to the source window.

8.4 Delay Until Appearance

Although the window is being distributed and that channel is requested for reception, a window will not appear at the receiver station until protocol has been detected from that window. In a situation where a client is only updated once every ten minutes, it may take up to ten minutes before the window appears at the receiver. A window that is never updated, will not appear at the receiver unless an expose event is caused at the source station forcing it to redraw the window.

A solution would be to make the receiver cause an expose event at the source as soon as a channel is requested for reception. This would prevent long delays before a rarely updated window appears.

8.5 Multiple Windows Per Client

To keep the amount of data to be distributed at reasonable levels, only windows that are currently being mapped should be sent. Child windows could include pop-up windows and pull-down menus, which probably should not be distributed.

8.6 Using the Display Sharing Wedge Approach

Use of the Display Sharing Wedge between the client and the server, instead of the modified server has some limits. The Wedge has a definite performance limit (see Section 7.1.2).

Other limiting factors of the Wedge approach include that clients must be started differently in order to be distributed. A client must be specifically attached to the Wedge when it is started. If it is not, it cannot be distributed without stopping and restarting it. Conversely, if a client is attached to Wedge when it is started, it cannot be unattached without being stopped.

The current version of Wedge is simply a stripped version of Xscope from the R4 MIT release. Some improvement in performance may be realized by writing a version of Wedge specifically optimized for Display Sharing.

8.7 Shared Memory and Semaphores

The Display Sharing prototype uses 24 semaphores and less than 32K bytes of shared memory. This must be accounted for when running the prototype to allow enough shared memory and semaphores for Display Sharing. The number of semaphores and the amount of shared memory can be set in the system configuration file.
8.8 Optimized X Code

The Display Sharing prototype's performance is directly affected by the efficiency of the clients that are being shared. To reduce network traffic, the number of X-Events, protocol packets and the number of round-trip requests should be kept to a minimum. This can be affected by the way the clients are designed.

Widgets enable creating clients simpler and faster, but they also reduce the efficiency of the client. Especially in cases where the standard Xlib libraries would be sufficient to create the client, using widgets would negatively affect the performance.

Xgks is a version of gks (Graphics Kernel System) which operates under the X environment. Xgks primitives are converted into X requests that are handled by the X server. Depending on the gks call, a word may be sent as separate characters instead of as a single word. Using Xgks instead of Xlib calls decreases the efficiency of the client.

8.9 Discontinued Distribution of Window

When the source removes a client from distribution, the receiver gets no indication of this, other than that the window is no longer being updated. Other ways of handling this could be to inform the receiver that the window is now static by changing its border.

8.10 Redundant Dedicated Hosts

Currently the Display Sharing system assumes only one dedicated host. The prototype can be modified to accept multiple dedicated hosts. If one host fails the Display Sharing System will try to compensate for it by using one of the other hosts. The LDM would show the combined channel guide from all hosts, and it would be transparent to the user which machine hosts any one channel. The number of redundant dedicated hosts can be set after the confidence level for the system is established.

8.11 Multiple Window Id's Over the Network

Currently the Display Sharing prototype does not handle the fact that window id's are not unique over several workstations. If two windows with identical window id's are being distributed from different workstations, and both are being received by the a third workstation, the receiver cannot be able to correctly attribute the incoming X-protocol to the correct window.

To solve this, additional information such as unique station id's, needs to be stored along with the window id's. Since all window id's on a single workstation are unique, the combination of a window id and a station id would insure that duplicate id's over a network do not exist.
8.12 gcml2 File

The /etc/mcgraphics/X11/gcml2 file must be compatible with the version of the modified server being used. The current modified server is compatible with the latest official release from MassComp, which is incompatible with the Ford Variant version. If the gcml2 file is incompatible with the modified server being used, it must be replaced by a compatible gcml2 file (see Section 4.2.1).
APPENDIX A

WORKSTATION LOCAL SHARED MEMORY

The Local Shared Memory structure shared between the server, PD, PR and LDM has the following fields:

semaphore:

An integer used to control access to shared memory area where protocol buffers used to pass data from the server to PD are stored. The semaphore is set and read by the server and by PD.

buf_stat[]:

An array of integers, indicating the state of each buffer which has one of the following values:

- MULTICAST : Set by multicast indicating that the buffer contains protocol to be distributed
- SM_EMPTY : Set by PD indicating that the buffer is currently empty

sm_status:

Integer set by LDM and used by PR, PD and multicast to indicate the status of the shared memory.

- SM_EMPTY : initialization value
- DIE : LDM has been requested to quit

start:

An integer used by LDM to indicate to multicast that it has authorized distribution on a new channel.

pd_alive:

Integer set by PD indicating when PD is alive and running.

pd_pid:

Integer set by PD containing the process id of the PD.

pr_init:

Integer set by PR indicating when PR is initialized.

pd_init:

Integer set by PD indicating when PD is initialized.
pm_port:
Unsigned short set by PR and LDM containing PM port number of the host where CDM was found.

pr_port:
Unsigned short set by PR containing PR port number.

distributor_id:
Integer set by PD containing the id number for the distributor.

pd_propagate_expose:
Integer set by PR indicating that PR has requested PD to send expose event to client.

expose_client:
XID set by PR indicating the window for PD to send the expose event back to

default_gc:
XID set by PR indicating the id of the source display's default graphics context.

root:
XID set by PR indicating the id of the source display's root.

wanted[]:
Array of integers indexed by client, set and used by multicast indicating if that client is to be distributed.

get_wat:
Integer set by PR indicating that PR wants PD to retrieve window attributes from the source by sending a request to PM.

send_wat:
Integer set by PR indicating that PR is requesting PD to send window attributes requested by PM.

wat_channel:
Integer set by PR indicating the channel for which PR is requesting PD to send the window attributes.
wat_bg_pixel:

Unsigned long set by PR containing the background pixel color for the window attributes that PR is requesting PD to send.

wat_parent:

XID set by PR containing the parent id of the window for which PR is requesting PD to send the window attributes.

wat_port:

Unsigned short set by PR and used by PD containing the receiver port that the window attributes are to be sent to

wat_id:

XID set by PR containing the graphics context id of the window attributes that PR is requesting PD to send.

wats:

An XWindowAttributes structure set by PR containing the window attributes that PR is requesting PD to send.

get_gc:

Integer set by PR indicating that PR wants PD to request graphics context info from PM.

send_gc:

Integer set by PR indicating that PR wants PD to send graphics context info to PM.

gc_channel:

Integer set by PR containing the source channel for which PD is requested to retrieve the graphics context info.

gc_id:

XID set by PR containing the id of the graphics context.

gc_port:

Unsigned short set by PR containing the receiver's port where PD sends the graphics context info once obtained.
pr_close_channel:

Integer set by LDM indicating to PR that there is a channel to be closed.

pr_close_client:

Integer set by LDM indicating to PR which channel to close.

clients[]:

An array of integers set by LDM indicating which client is being distributed on each channel.

source_default_gc[]:

An array of unsigned longs set by LDM and used by PR containing the default graphics context for each channel.

source_root[]:

An array of unsigned longs set by LDM and used by PR containing the source root id for each channel.

gcwin[]:

Array of GCWIN structures set by multicast containing information about the each local graphics context.

The GCWIN structure contains the following fields:

gid : XID containing the graphics id
window : XID containing the window id
mask : Unsigned long with bits set to indicate which GC values are used
GCValues : XGCValues structure of graphics context values

win[]:

Array of WIN structures set by multicast containing information about each local window.

The WIN structure contains the following fields:

window : XID containing the window id
background : Unsigned long containing the background pixel color for the window attributes
parent : XID containing the window id of the parent window
client[]:

Array of integers set by multicast and used by PD indicating the client id of the corresponding X Protocol buffer.

len[]:

Array of integers set by multicast and used by PD indicating the length of the corresponding X Protocol buffer.

window:

XID set by LDM and used by multicast containing the id of the window to be distributed.

xbuffer[][]:

Array of buffers of unsigned characters written by multicast and read by PD, containing X packet data to be distributed.

management_host[]:

Character string set by PR and LDM and used by PD containing the host name for the Central Distribution Manager.
The Dedicated Host Shared Memory structure has the following fields:

**sm_status:**

- Integer indicating the status of the shared memory. The following values are possible:
  - AOK : initialization value
  - PM_DIE : CDM is requested to quit

**read_pipe:**

- Integer set by CDM and used to indicate to PM that there is a new Channel Map.

**pm_port:**

- Unsigned short set by PM and used by CDM containing the PM port number.

**new_source_channel:**

- Integer set by CDM to indicate to PM that the new source channel has been added to the downloaded channel map.

**remv_source_channel:**

- Integer set by CDM to indicate to PM that the source channel has been removed in the downloaded channel map.

**new_receiver_channel:**

- Integer set by CDM to indicate to PM that the new receiver channel has been added to the downloaded channel map.

**remv_receiver_channel:**

- Integer set by CDM to indicate to PM that the receiver channel has been removed in the downloaded channel map.

**station_index:**

- Integer set by CDM and used by PM containing the index of the distributing station.
source_default_gc[]:

An array of unsigned longs set and used by CDM containing the default graphics context for each channel.

source_root[]:

An array of unsigned longs set and used by CDM containing the source root id for each channel.

dest_fd[][]:

Array of integers set and used by PM containing by channel and by receiver all receiver file descriptors actively receiving protocol on each channel.

source_fd[]:

Array of integers set and used by PM containing by channel the file descriptors that are active sources for each channel.

Stations[]:

Array of Stations structures to describe a workstation configured with a Protocol Distributor and a Protocol Receiver. The structure values are set and used in CDM and PM. For a description of the individual structure members, see Appendix J.

ChanMap[]:

Array of ChanMap structures to hold channel map information. The structure values are set and used in CDM and PM. For a description of the individual structure members, see Appendix J.

source_name[][]:

Array of character strings set by CDM containing the source name for each channel.

channel_bytes[]:

Array of unsigned longs to store accumulated byte counts passing through PM for each channel. Used for LAN traffic measurement.

receiver_bytes[]:

Array of unsigned longs to store accumulated byte counts passing through PM for each receiver. Used for LAN traffic measurement.
distributor_bytes[]:

Array of unsigned longs to store accumulated byte counts passing through PM for each distributor. Used for LAN traffic measurement.

no_of_packets[]:

Unsigned long containing the accumulated count of packets passing through PM. Used for LAN traffic measurement.
APPENDIX C

I/O REQUEST TYPES

The I/O Request Types

NOOP:

No operation request.

X_DATA:

Indicates that an X Data packet will follow.

EXPOSE:

Used to request an expose event from the source.

GWATS:

Used to request Window Attributes from the source.

GGCS:

Used to request Graphics Context State from the source.

WATS:

Used to send Window Attributes to the receiver.

GCS:

Used to send Graphics Context State to the receiver.

SHUTCOMP:

Used to indicate that shutdown of receiver channel is complete.
APPENDIX D

RPC REQUEST CODES

CDM_GET_LIST
- Request to retrieve the channel map - id list.

CDM_DIST_REQ
- Distribution Authorization Request.

CDM_RECV_REQ
- Reception Authorization Request.

CDM_REMV_CHAN
- Request to remove a channel.

CDM_REMV_RECV
- Request to remove a receiver from the linked list.

CDM_PRESENT
- Broadcast request to locate dedicated host.

CDM_REG_DIST
- Register a Distributor Request.

CDM_REG_RECV
- Register a Receiver Request.

CDM_GO_AWAY
- Request to go away, exit.
APPENDIX E

RPC DATA STRUCTURE FOR RETRIEVE TV GUIDE

Input structure:

Void

Output structure:

tv_guide[] : Array of strings of characters, one string per channel.
APPENDIX F

RPC DATA STRUCTURE FOR DISTRIBUTION AUTHORIZATION

Input structure:

ChanID

- chanid[] : Array of characters containing the source name
- hostname[] : Array of characters containing the host name
- distributor_id : Integer containing the id number for the distributor
- pr_port : Unsigned short containing PR port number
- default_gc : Unsigned long containing the XID of the default graphics context
- root : Unsigned long containing the XID of the source root
- xid : Unsigned long containing the client xid

Output structure:

DstAuth :

- authorization : Integer indicating whether distribution is authorized
- channel : Integer indicating channel to distribute on
- pm_port : Unsigned short indicating port number
APPENDIX G

RPC DATA STRUCTURE FOR RECEPTION AUTHORIZATION

Input structure:

ChanReq :
- channel : Integer indicating channel to receive on
- hostname[] : Array of characters containing the host name
- distributor_id : Integer containing the id number for the distributor
- pr_port : Unsigned short containing PR port number

Output structure:

RecvAuth :
- authorization : Integer indicating whether distribution is authorized
- pm_port : Unsigned short indicating port number
- default_gc : Unsigned long containing the XID of the default graphics context
- root : Unsigned long containing the XID of the source root
APPENDIX H

RPC DATA STRUCTURE FOR CANCEL DISTRIBUTION

Input structure:

channel : Integer indicating channel to remove.

Output structure:

retval : Integer indicating whether request was successful.
APPENDIX I

RPC DATA STRUCTURE FOR CANCEL RECEPTION

Input structure:

RemvRecv :

- channel : Integer indicating channel to remove
- portnum : Unsigned short indicating port number

Output structure:

- retval : Integer indicating whether request was successful
APPENDIX J

CHANNEL MAP AND STATION STRUCTURES

ChanMap:

Array of ChanMap structures to hold channel map information. The structure has the following members:

- **num_receivers**: Integer set and used by PM and CDM, indicating number of receivers for this channel
- **client_id**: Integer set by CDM and used by PM indicating client number for this channel
- **recv_ports[]**: Array of unsigned shorts set and used by PM and CDM, containing the port numbers of each receiver
- **recv_hostname[][]**: Array of character strings set by CDM containing the port name for each receiver
- **source_hostname[]**: Character string set by PM and CDM and used by PM, containing the source name for this channel

Stations:

Array of Stations structures to describe a workstation configured with a Protocol Distributor and a Protocol Receiver. The structure has the following members:

- **pd_fd**: Integer set by PM and used by PM and CDM, indicating file descriptor for PM to read from
- **pr_fd**: Integer set and used by PM, indicating file descriptor for PM to write to
- **num_channels**: Integer set by PM and used by PM and CDM, indicating number of channels this station is distributing on
- **dist_channel[]**: Array of integers set and used by PM, containing channel numbers of active channels
- **dist_client[]**: Array of integers set by CDM and used by PM, containing client being distributed on each associated dist_channel
- **hostname[]**: Character string set by CDM and used by PM, indicating name of host for distributor
APPENDIX K
SERVER LISTINGS

The included program listings are prototypes, no warranty is expressed or implied for their use in any other fashion. They should not be considered or used as production software. The information in the listings is supplied on an "as is" basis. No responsibility is assumed for damages resulting from the use of any information contained in the listings.

The software in these listings has been compiled on Masscomp 6350's and 6600's and on Sun 3's and 4's. Modifications may be necessary for use on other systems.

>Title: Initialize the tv guide and channel map

This routine initializes the TV guide and channel map. It iterates through all channels and initializes each channel's receiver ports and destination file descriptor. It also sets the channel's source hostname to an empty string. Similarly, it iterates through all stations and initializes their PD and PR file descriptors, as well as their number of channels. For each channel within a station, it sets the channel's destination and client descriptors to -1. Finally, it sets the station's hostname to an empty string.

---

*/

Title: Create Protocol Multiplexer and Pipe

This routine creates the Protocol Multiplexer and a pipe to the Multiplexer for communications. It defines several variables, including `pid`, `readfd`, `writefd`, `sid`, `byte`, and `bytes_read`. These variables are used to create the pipe and multiplexer. The routine sets `bytes_read` to 0.
static struct sockaddr_in svinh = { AF_INET };

This routine creates a shared memory area.

```c
int create_shared_memory()
{
    #define RWMODE 0666

    #ifdef TRACE
        fprintf(stderr,"CDM::cdm_key:%d\n",CDM_KEY);
        fprintf(stderr,"CDM::sizeof(struct CDM_SHMEMORY):Ox%x\n",sizeof(struct CDM_SHMEMORY));
    #endif

    /* attach to shared memory */
    shmid = shmget((int)CDM_KEY,sizeof(struct CDM_SHMEMORY),IPC_CREAT|RWMODE);
    if (shmid<0) {
        perror("CDM::shmget (create_shared_memory):");
        go_away();
    }
    shmem = (struct CDM_SHMEMORY *)shmat(shmid,0,0);
    if (shmem==0) {
        perror("CDM::shmat (create_shared_memory):");
        go_away();
    }

    return(shmid);
}
```

This routine replaces exit, and in fact calls it. It also may be used to perform housekeeping.

```c
/*
  * Get rid of the shared memory identifier.
  */
  shmctl(shmid,IPC_RMID,0);
/*
0 - 7
```
* Tell someone we are going away.
*/
    fprintf(stderr, "CDM:: EXITING.......\n");
    sleep(2);
    exit(0);
} /* end go_away */

/* This interface must manage two items concerning remote procedure calling:
* 1) An arbitrary number of transport connections upon which rpc requests
* are received. The two most notable transports are TCP and UDP; they
* are created and registered by routines in svc_tcp.c and svc_udp.c,
* respectively;
* they in turn call xprt_register and xprt_unregister.
* 2) An arbitrary number of locally registered services. Services are
* described by the following four data: program number, version number,
* "service dispatch" function, a transport handle, and a boolean that
* indicates whether or not the exported program should be registered with
* a local binder service; if true the program's number and version and the
* port number from the transport handle are registered with the binder.
* These data are registered with the rpc svc system via svc_register.
* A service's dispatch function is called whenever an rpc request comes in
* on a transport. The request's program and version numbers must match
* those of the registered service. The dispatch function is passed two
* parameters, struct svc_req * and SVCXPRT *, defined below.

/* When the service routine is called, it must first check to see if it
 * knows about the procedure; if not, it should call svcerr_noproc
 * and return. If so, it should deserialize its arguments via
 * SVC_GETARGS (defined above). If the deserialization does not work,
 * svcerr_decode should be called followed by a return. Successful
 * decoding of the arguments should be followed the execution of the
 * procedure's code and a call to svc_sendreply.
 *
 * Also, if the service refuses to execute the procedure due to too-
 * weak authentication parameters, svcerr_weakauth should be called.
 * Note: do not confuse access-control failure with weak authentication!
 *
 * NB: In pure implementations of rpc, the caller always waits for a reply
 * msg. This message is sent when svc_sendreply is called.
 * Therefore pure service implementations should always call
 * svc_sendreply even if the function logically returns void; use
 * xdr.h - xdr_void for the xdr routine. HOWEVER, tcp based rpc allows
 * for the abuse of pure rpc via batched calling or pipelining. In the
 * case of a batched call, svc_sendreply should NOT be called since
 * this would send a return message, which is what batching tries to avoid.
 * It is the service/protocol writer's responsibility to know which calls
 * are
 * batched and which are not. Warning: responding to batch calls may
 * deadlock the caller and server processes!

/* Modified for Masscomp kernel 3/87 by Bob Doolittle */

/*
 XDR provides a conventional way for converting between C data
types and an external bit-string representation. Library supplied
routines provide for the conversion on built-in C data types. These
routines and utility routines defined here are used to help implement
a type encode/decode routine for each user-defined type.

Each data type provides a single procedure which takes two arguments:

bool_t
xdrproc(xdrs, argresp)
    XDR *xdrs;
    <type> *argresp;

xdrs is an instance of a XDR handle, to which or from which the data
type is to be converted. argresp is a pointer to the structure to be
converted. The XDR handle contains an operation field which indicates
which of the operations (ENCODE, DECODE or FREE) is to be performed.

XDR DECODE may allocate space if the pointer argresp is null. This
data can be freed with the XDR_FREE operation.

We write only one procedure per data type to make it easy
to keep the encode and decode procedures for a data type consistent.
In many cases the same code performs all operations on a user defined
type,
because all the hard work is done in the component type routines.
decode as a series of calls on the nested data types.
*/

/*
 Xdr operations. XDR_ENCODE causes the type to be encoded into the
stream. XDR_DECODE causes the type to be extracted from the stream.
XDR_FREE can be used to release the space allocated by an XDR_DECODE
request.

 * In-line routines for fast encode/decode of primitive data types.
 * Caveat emptor: these use single memory cycles to get the
 * data from the underlying buffer, and will fail to operate
 * properly if the data is not aligned. The standard way to use these
 * is to say:
 * if ((buf - XDR_INLINE(xdrs, count)) = NULL)
 * return (FALSE);
 * <<< macro calls >>>
 * where 'count' is the number of bytes of data occupied
 * by the primitive data types.
 * N.B. and frozen for all time: each data type here uses 4 bytes
 * of external representation.
