ABSTRACT

The Rich-burn/Quick-mix/Lean-burn (RQL) combustor has been identified as a potential gas turbine combustor concept to reduce NOX emissions in High Speed Civil Transport (HSCT) aircraft. To demonstrate reduced NOX levels, cylindrical flamentube versions of RQL combustors are being tested at NASA Lewis Research Center. A critical technology needed for the RQL combustor is a method of quickly mixing by-pass combustion air with rich-burn gases.

In this study, jet mixing in a cylindrical quick-mix section was numerically analyzed. The quick-mix configuration was five inches in diameter and employed twelve radial-inflow slots. The numerical analyses were performed with an advanced, validated 3-D Computational Fluid Dynamics (CFD) code named REFLEQS. Parametric variation of jet-to-mainstream momentum flux ratio (J) and slot aspect ratio was investigated. Both non-reacting and reacting analyses were performed.

Results showed mixing and NOX emissions to be highly sensitive to J and slot aspect ratio. Lowest NOX emissions occurred when the dilution jet penetrated to approximately mid-radius. The viability of using 3-D CFD analyses for optimizing jet mixing was demonstrated.

INTRODUCTION

In order to meet the growing need for faster transportation, High-Speed Civil Transport (HSCT) aircraft and associated propulsion systems have been under study in recent years. One major concern that has surfaced concerning HSCT engines is their impact on deteriorating the earth's ozone layer. Using current technology, a fleet of HSCT aircraft would produce large amounts of oxides of nitrogen (NOX) while cruising in the stratosphere. Such high levels of NOX, through a series of well known reactions, would drastically reduce ozone levels. In order to reduce NOX emissions, technology must be developed to design advanced, low emission combustors.

One combustor concept that has been identified as a leading candidate to reduce NOX emissions is the Rich-burn/Quick-mix/Lean-burn (RQL) combustor. Originally conceived and developed for industrial combustors (Mosier and Pierce, 1980 and Pierce et al., 1980), the RQL concept utilizes staged burning, as shown in Figure 1. Combustion is initiated in a fuel rich zone at equivalence ratios between 1.2 and 1.8, thereby reducing NOX formation by depleting the available oxygen. Bypass combustion air is introduced in a quick-mix section and lean combustion occurs downstream at an overall equivalence ratio between 0.5 and 0.7. The quick-mix section usually has a smaller geometric cross-section area than the rich burn zone in order to prevent backflow and enhance mixing.

![Fig. 1. Industrial Rich-burn/Quick-mix/Lean-burn (RQL) Combustor (Pierce et al., 1980)](image-url)
Tacina (1990) has shown RQL NOx levels to be higher than lean, premixed combustor NOx levels. The higher NOx emissions for RQL were attributed to stoichiometric burning in the quick-mix section, thus emphasizing the need for optimized rapid mix concepts. Indeed, Nguyen et al. (1989) have shown that instantaneous mixing is assumed in the quick-mix section, low NOx emission index can be obtained at HSC1 cruise flight conditions. Hence, one challenge of the RQL concept is to identify quick-mix sections with rapid mixing.

This study sought to investigate the influence of jet-to-mainstream momentum flux ratio (J) and slot aspect ratio (SAR) on mixing effectiveness in a RQL flammeter combustor to be tested at NASA Lewis Research Center (LeRC). Conventionally, dilution air in can combustors has been introduced through radial inflow holes. According to Holdeman’s correlation (Holdeman et al., 1987), optimum mixing occurs when the following expression is satisfied:

\[ n = \pi \frac{\sqrt{J}}{C} \]  

where

- \( n \) = optimum number of holes
- \( C \) = experimentally derived constant -2.5
- \( J \) = jet-to-mainstream momentum flux ratio (\( \rho_j \frac{V_j^2}{\rho_m V_m^2} \)).

Unfortunately, this correlation was developed for circular holes dilution jet mixing and jet mass flow-to-mainstream mass flow ratios (\( m_j/m_m \)) of approximately 0.5. The RQL combustor requires \( m_j/m_m \) of 2.0, thus necessitating slots instead of holes around the can’s perimeter. The design of slots for optimum mixing needs further investigation, and was the focus of this study.

**CFD Code**

The approach in this study was to perform 3-D numerical computations on a cylindrical quick-mix section. The goal of the study was to provide improved understanding of slot injection and mixing. An advanced CFD code, REFLEQS, was used to perform the computations. REFLEQS was developed by CFD Research Corporation (Przekwas et al., 1990 and Smith et al., 1988) to analyze turbulent, reacting flows. The basic capabilities/methodologies in REFLEQS include:

1. solution of two and three-dimensional Navier-Stokes equations for incompressible and compressible flows;
2. cartesian, polar, and non-orthogonal body-fitted coordinates;
3. porosity-resistivity technique for flows with internal blockages;
4. fully implicit and strongly conservative formulation;
5. three differencing schemes: upwind, hybrid, and central differencing with damping terms;
6. standard (Lauder and Spalding, 1974) and extended (Chen and Kim, 1987) k-\( \varepsilon \) turbulence models, the two-scale turbulence model of Kim and Chen (1988), and the low-\( \varepsilon \)-Reynolds number k-\( \varepsilon \) model of Chien (1985);
7. instantaneous, one-step, and two-step combustion models;
8. modified form of Stone’s Strongly Implicit Solver; and
9. pressure-based solution algorithms including SIMPLE and a variant of SIMPLC.

REFLEQS has undergone a considerable amount of systematic quantitative validation for both incompressible and compressible flows. Over 30 validation cases have been performed to date, and good-to-excellent agreement between benchmark data and predictions has been shown (Smith et al., 1989; Ralcliff and Smith, 1989; and Arva et al., 1990). The good agreement gives confidence in the numerical results of this study.

**HEAT RELEASE MODEL**

After reviewing the time scales for heat release at cruise-type conditions in RQL mixers, it was determined reaction rates were much faster than mixing rates. Hence, the combustion process was considered mixing controlled, and instantaneous reaction rates for heat release were assumed.

When rich burn gases (composed of equilibrium concentration of CO, CO2, H2, H2O, and N2) were mixed with air, they were assumed to react according to the equation:

\[ 0.0570 \text{CO} + 0.0197 \text{CO}_2 + 0.0383 \text{H}_2 + 0.0680 \text{H}_2\text{O} + 0.1371 \text{N}_2 + 0.1047 \text{O}_2 + 0.3953 \text{N}_2 \rightarrow 0.0767 \text{CO}_2 + 0.1063 \text{H}_2\text{O} + 0.7123 \text{N}_2 + 0.0565 \text{O}_2 \]  

Accordingly, any CO concentration that remained in the mixer exit was the result of unmixedness.

**NOx MODEL**

It was assumed that the NOx reactions did not contribute to the overall heat release in the combustor, thus allowing the NOx reactions to be “decoupled” from the heat release reactions. NOx was calculated as a passive scalar after the computation of the reacting flowfield.

A simple Zeldovich reaction scheme was used to model the NOx formation. According to the mechanism, NO formation can be described by:

\[ \text{N}_2 + \text{O} \leftrightarrow \text{NO} + \text{N} \]  

and

\[ \text{O}_2 + \text{N} \leftrightarrow \text{NO} + \text{O}. \]  

The first reaction is much slower than the second one and hence controls the rate of NO formation. If the concentration of NO is much smaller than the corresponding equilibrium value, the rate equation for NO can be written as:

\[ \frac{d(\text{NO})}{dt} = K [\text{N}_2][\text{O}] \]  

Approximating the concentrations of \( \text{N}_2 \) and \( \text{O} \) by the local equilibrium values, the rate equation is given by

\[ \frac{d(\text{NO})}{dt} = A e \left( \frac{K}{[\text{N}_2][\text{O}]^2} \right) \]  

From Quan et al. (1972), the rate constants were determined to be:

\[ A = 5.74 \times 10^4 1.1 \sec \sqrt{\text{moles}} \text{m}^3 \]  

\[ K = 6.7 \times 10^{-13} \text{K} \]  

The NOx model was calibrated against the experimental results of Anderson (1975), who used a premixed, prevaporized laboratory combustor. The REFLEQS test case consisted of premixed propane and air reacting in a straight channel and instantaneous heat release. The rate constants had to be modified to give good agreement with Anderson’s data. The final constants used in this study were:

\[ A = 3.3 \times 10^4 \sec \sqrt{\text{moles}} \text{m}^3 \]  

\[ K = 1.03 \times 10^{-14} \text{K} \]
Figure 2 shows the computed results compared to Anderson's data of Emission Index (EI) as a function of adiabatic Flame temperature.

**Fig. 2. Calibration of NO\textsubscript{x} Model in REFLEQS**

Details of Numerical Model

A geometry compatible with the NASA LeRC flamtube combustor was selected for analysis. The geometry, numerical grid, numerical details, boundary conditions, grid independence, and convergence criteria are discussed below.

**Geometry**

The geometry of the numerical model consisted of three components: an inlet pipe, converging section and a quick-mix section (see Figure 3). The inlet pipe was 0.152 m (6.0 in.) in diameter and 0.076 m (3.0 in.) in length. The inlet pipe converged into the quick-mix section which was 0.127 m (5.0 in.) in diameter (D). The length of the quick-mix section was 0.333 m (13.0 in.). In reality, the length of actual quick-mix section hardware is approximately 6 inches, but the computational domain is extended for better understanding of NO\textsubscript{x} formation and to eliminate flowfield contamination by exit boundary conditions.

Twelve slots were located symmetrically around the perimeter of the quick-mix section. The axial location of the slot centerline was 0.076 m (3.0 in.) from the inlet of the quick-mix section. The baseline slots were rectangular in shape with an aspect ratio of four and aligned in the streamwise direction. Three variations in slot aspect ratio (SAR) were tested: 1, 4 and 16.

Due to geometric symmetry, only one slot was modeled with planes of symmetry set up halfway between adjacent slots. This allowed greater grid resolution and reduction of computer turnaround time. The \( r_0 \) domain was reduced to a pie section with a central angle of thirty degrees.

**Grid**

A baseline grid of 9,216 cells (32x16x18 in \( x, r, \theta \) directions) was selected and used for modeling the mixer. The grid is shown in Figure 4. Note that the origin of the coordinate system is located at the center of the slot. The axial grid spacing is dense near the slot, and gets coarser upstream and downstream of the slot. The grid in the radial direction was non-uniform with greater density near the combustor wall (power expansion of 1.2). The grid in the transverse direction was uniform in the slot, and slowly expanding away from the slot. The baseline slot was represented by a 6x6 mesh. As will be discussed in grid independence studies, this rather coarse grid is not grid-independent, but it does capture all of the relevant flow features. For comparative studies, it was felt sufficient.

**Numerical Details**

The numerical details of the calculations included:

1. Whole field solution of \( u \)-momentum, \( v \)-momentum, \( w \)-momentum, pressure correction, turbulent kinetic energy \( k \), dissipation rate \( \varepsilon \), total enthalpy, and mixture fraction;
2. Upwind Differencing for parametric studies of \( J \) and central differencing for parametric studies of SAR;
3. Variable Fluid Properties (i.e. temperature dependency of specific heat, laminar viscosity, etc.);
4. Adiabatic Walls;
5. Standard \( k-e \) Model with wall functions;
6. Turbulent Prandtl number of 0.9;
7. Instantaneous heat-release model; and
8. Six active chemical species.

A geometry compatible with the NASA LeRC flamtube combustor was selected for analysis. The geometry, numerical grid, numerical details, boundary conditions, grid independence, and convergence criteria are discussed below.

**Geometry**

The geometry of the numerical model consisted of three components: an inlet pipe, converging section and a quick-mix section (see Figure 3). The inlet pipe was 0.152 m (6.0 in.) in diameter and 0.076 m (3.0 in.) in length. The inlet pipe converged into the quick-mix section which was 0.127 m (5.0 in.) in diameter (D). The length of the quick-mix section was 0.333 m (13.0 in.). In reality, the length of actual quick-mix section hardware is approximately 6 inches, but the computational domain is extended for better understanding of NO\textsubscript{x} formation and to eliminate flowfield contamination by exit boundary conditions.

Twelve slots were located symmetrically around the perimeter of the quick-mix section. The axial location of the slot centerline was 0.076 m (3.0 in.) from the inlet of the quick-mix section. The baseline slots were rectangular in shape with an aspect ratio of four and aligned in the streamwise direction. Three variations in slot aspect ratio (SAR) were tested: 1, 4 and 16.

Due to geometric symmetry, only one slot was modeled with planes of symmetry set up halfway between adjacent slots. This allowed greater grid resolution and reduction of computer turnaround time. The \( r_0 \) domain was reduced to a pie section with a central angle of thirty degrees.

**Grid**

A baseline grid of 9,216 cells (32x16x18 in \( x, r, \theta \) directions) was selected and used for modeling the mixer. The grid is shown in Figure 4. Note that the origin of the coordinate system is located at the center of the slot. The axial grid spacing is dense near the slot, and gets coarser upstream and downstream of the slot. The grid in the radial direction was non-uniform with greater density near the combustor wall (power expansion of 1.2). The grid in the transverse direction was uniform in the slot, and slowly expanding away from the slot. The baseline slot was represented by a 6x6 mesh. As will be discussed in grid independence studies, this rather coarse grid is not grid-independent, but it does capture all of the relevant flow features. For comparative studies, it was felt sufficient.

**Numerical Details**

The numerical details of the calculations included:

1. Whole field solution of \( u \)-momentum, \( v \)-momentum, \( w \)-momentum, pressure correction, turbulent kinetic energy \( k \), dissipation rate \( \varepsilon \), total enthalpy, and mixture fraction;
2. Upwind Differencing for parametric studies of \( J \) and central differencing for parametric studies of SAR;
3. Variable Fluid Properties (i.e. temperature dependency of specific heat, laminar viscosity, etc.);
4. Adiabatic Walls;
5. Standard \( k-e \) Model with wall functions;
6. Turbulent Prandtl number of 0.9;
7. Instantaneous heat-release model; and
8. Six active chemical species.
Velocity and pressure were obtained from experimental test plans for the RQL flametube combustor. A uniform velocity profile was assumed with a turbulent intensity typical of primary zones in gas turbine combustors and a turbulent length scale corresponding to a turbulent viscosity 1000 times greater than laminar viscosity. The mainstream inlet conditions (at 6.0 in. diameter) were:

- Axial velocity = 355 m/s
- Temperature = 2221°K
- Density = 2.32 kg/m³
- Composition (mass fraction) = 0.134 CO, 0.068 CO₂, 0.006 H₂, 0.096 H₂O, 0.696 N₂
- Turbulent intensity (u'/U) = 50%
- Turbulent length scale (l/Δx) = 0.02

Since equilibrium NOₓ levels are very low for φ of 1.6 (= 4 ppm), no NOₓ was assumed in the mainstream inlet.

**Jet Inlet.** The composition at the dilution jet inlet was assumed to be air. A uniform velocity profile was assumed and turbulent properties were selected using the same logic as discussed for mainstream turbulence. The jet inlet flow conditions were:

- Mass flux ratio (m_j/m_a) = 1.94
- Jet temperature = 811°K
- Density = 6.35 kg/m³
- Composition (mass fraction) = 0.232 O₂, 0.768 N₂
- Turbulent intensity (v'/V) = 10%
- Turbulent length scale (l/D) = 0.13

The momentum flux ratio (J) was varied parametrically from 16 to 64 by variation of jet velocity from 120 m/s to 240 m/s. The jet velocity variation corresponded to liner pressure drops (ΔP/1) of 3 to 12 percent. For each jet velocity, the slot flow area was modified to maintain constant jet flow.

**Exit Boundary.** The exit boundary condition was a zero gradient boundary condition.

**Transverse Boundaries.** The transverse boundaries were assumed to be symmetry planes. These boundaries were also tested for possible outflow by setting them to be periodic boundaries. No discernable difference was seen between cases with symmetric and periodic transverse boundaries.

**Combustor Wall.** The combustor wall was treated as a no-slip adiabatic wall (zero enthalpy gradient). Wall functions were used for the calculations of wall shear stress and near-wall turbulent quantities (k and ε).

**Centerline.** The computational boundary at the centerline was assumed to be a symmetry plane.

**Grid Independence.**
Two different sizes of grids were run to test grid independence: 9,216 and 52,650 cells. The finer grid was obtained by increasing the grid density by ~75% in all three directions. Comparison of the two grids is shown in Figure 5.

Computational results from the two grids are presented in Figure 6 for a momentum flux ratio (J) of 32.0. The isotherms in an rx plane through the jet centerline are shown and compared. Qualitatively they exhibit similar features, although the jet penetrated a little further in the case of the fine grid. Isotherms are also shown for two axial planes: x/D = 0.0 and 2.0. The isotherms at x/D = 2.0 show slightly higher temperatures (~22°K) for the fine grid. Also, the cold region in the fine grid solution is located closer to the centerline, indicating greater penetration. However, overall the coarse grid solution is very similar to the fine grid solution.

Based on this grid-independence study, it appears the coarse grid captures the overall physics of the problem, and can be used to qualitatively compare quick-mix designs.
Convergence

The summations of all error residuals were reduced five orders of magnitude, and continuity was conserved in each axial plane. Typically, convergence required approximately 150 iterations as shown in the Figure 7. The relaxation on the velocity components (u and v only) was continuously varied during the run through a user specified input file. The repeated variation of relaxation allowed resolution of different scales of numerical error. This was found to speed up convergence by a factor of six compared to constant relaxation. Approximately 3 CPU hours were required on an Alliant FX/8 mini-supercomputer (operating on one computational element). Fine grid calculations took approximately 500 iterations and 40 CPU hours. For comparison, the ALLIANT computer speeds are ~20 times slower than a CRAY X-MP.

RESULTS

Parametric numerical tests were performed for jet-to-mainstream momentum flux ratios (J), for both non-reacting and reacting gases. Parametric variation of slot aspect ratio (SAR) was also studied. Discussion of the findings are reported below.

Variation of J: Non-Reacting Flow

Five jet-to-mainstream momentum flux ratios were parametrically tested: 16, 32, 40, 48, and 64. All other flow conditions were held constant, including mass flow ratio (jet-to-mainstream) at 1.94. To maintain a constant mass flow, the slot size was changed for each J. The slot aspect ratio was held constant at four, and was always centered at the same location. The same number of grid cells were used in all cases. However, since the slot size was changing, the grid density had to be slightly altered for each case. This variation is thought to have a minimal effect on the results discussed below.

Computed temperature contour maps are presented at x/D of 1.0, as shown in Figure 8. The radial location of the lowest temperatures indicates the penetration location of the cold jet. As expected, increased jet penetration can be seen for larger values of J. Best mixing seems to occur when the jet penetrates to approximately mid-radius. J of 32 and J of 40 appear to be optimum mixers. For comparison, the optimum J is 45.6 using Eq. (1).
Fig 8. Temperature Contour Maps for Non-Reacting Conditions: $x/D=1.0$
Fig 10. Temperature Contour Maps for Reacting Conditions: \( x/D = 1.0 \)
For a more quantitative comparison of mixing effectiveness, the mass-weighted standard deviation of temperature ($\sigma_T$) was calculated for each case. $\sigma_T$ was defined as:

$$\sigma_T = \sqrt{\frac{\sum m_i(T_i - T_{avg})^2}{\sum m_i}}$$

In Figure 9, $\sigma_T$ is presented versus $J$. It can be seen that $J$ of 32 has the lowest $\sigma_T$ at $x/D = 2.0$. Underpenetration is worse than overpenetration in terms of $\sigma_T$.

**Variation of $J$: Reacting Flow**

The same cases were analyzed as discussed above, except chemical reaction was turned on. Due to reaction, the overall mass-averaged exit temperature increased from 1301°K for non-reacting flows to 1790°K for reacting flows. Figure 10 shows temperature contour maps for the reacting cases one diameter downstream of the jet center. From this figure, it appears that $J = 40$ is the best mixer. This can be further elucidated by looking at the mixing effectiveness ($\sigma_T$) shown in Figure 11. Figure 11 shows $J = 40$ to be the best mixer at $x/D = 1.0$ and $2.0$.

The NO$_x$ results are presented in terms of Emission Index (EI) in Figure 13. For the optimum case ($J_{opt}=40$), EI is 2.9 at $x/D = 2.0$. Significant increase in EI is predicted as $J$ is increased or decreased from the optimum value. For $J$ greater than $J_{opt}$, jet overpenetration causes jet backflow on the centerline, resulting in higher NO$_x$ emissions. For $J$ less than $J_{opt}$, underpenetration of the jet results in reaction (and high temperatures) on the combustor centerline.
Figure 14 shows NO\(_x\) concentrations convected out of each axial plane. Except for \(J = 16\), all the cases show very little NO\(_x\) formation downstream of \(x/D = 1.0\). This indicates that high temperature zones are no longer existent. For the \(J = 16\) case, NO\(_x\) formation is increasing significantly downstream of \(x/D = 1.0\), indicating high temperature and chemical reaction is still taking place.

These results suggest the importance of SAR on NO\(_x\) emissions. As was shown earlier for \(J\) variation, the jet must penetrate to approximately mid-radius for optimum mixing, and hence lowest NO\(_x\).
CONCLUSIONS

The overall conclusions of this study were:

1. The viability of using 3-D CFD to model and screen quick-mix concepts of low emission combustors was successfully demonstrated.

2. A five-inch diameter quick-mix section compatible with the NASA LeRC Low Emission Combustor Program was numerically analyzed. The configuration consisted of twelve, radial-inflow slots uniformly distributed around the perimeter of the quick-mix section. Optimum mixing for non-reacting flow occurred for a jet-to-mainstream momentum flux ratio (J) between 32 and 40. For reacting flow, the NOx emission index was shown to be highly sensitive to J, with the lowest value of 2.9 calculated for J of 40 (at x/D = 2.0).

3. The numerical results suggest that slot aspect ratio has a pronounced effect on jet penetration and mixing effectiveness. Conventional correlations for optimum mixing effectiveness for holes may not be applicable for slots.

# CFD Analysis of Jet Mixing in Low NOX Flametube Combustors

## Abstract
The Rich-burn/Quick-mix/Lean-burn (RQL) combustor has been identified as a potential gas turbine combustor concept to reduce NOX emissions in High Speed Civil Transport (HSCT) aircraft. To demonstrate reduced NOX levels, cylindrical flametube versions of RQL combustors are being tested at NASA Lewis Research Center. A critical technology needed for the RQL combustor is a method of quickly mixing by-pass combustion air with rich-burn gases. In this study, jet mixing in a cylindrical quick-mix section was numerically analyzed. The quick-mix configuration was five inches in diameter and employed twelve radial-inflow slots. The numerical analyses were performed with an advanced, validated 3-D Computational Fluid Dynamics (CFD) code named REFLEQS. Parametric variation of jet-to-mainstream momentum flux ratio (J) and slot aspect ratio was investigated. Both non-reacting and reacting analyses were performed. Results showed mixing and NOX emissions to be highly sensitive to J and slot aspect ratio. Lowest NOX emissions occurred when the dilution jet penetrated to approximately mid-radius. The viability of using 3-D CFD analyses for optimizing jet mixing was demonstrated.
