PREFACE

Current hardware verification efforts have only begun to address the problem of composing asynchronously communicating units. This report presents work underway to formally specify and verify a floating-point coprocessor based on the MC68881. Our work uses the HOL verification system developed at Cambridge University. The coprocessor consists of two independent units: the bus interface unit to communicate with the CPU and the arithmetic processing unit to perform the actual calculation. We illustrate how the specification and verification process can be organized and simplified by a generalized hierarchical decomposition methodology that supports reasoning about horizontal interaction between processes. Techniques of composing processes having independent time scales are formalized. Reasoning about the interaction and synchronisation among processes using higher-order logic is demonstrated.

The CPU instructions and the floating-point instructions are allowed to execute concurrently to improve performance. However, the coprocessor interface is designed to maintain a strictly sequential execution model to reflect the assembly language programmer’s view of the system. We discuss the combination of the CPU and the coprocessor to form a computer system, and explore techniques to map from the underlying concurrent implementation to the programmer’s view of sequential execution of instructions.

The NASA technical monitor for this work is Sally C. Johnson of NASA Langley Research Center, Hampton, Virginia.

The work was done at Boeing Military Airplanes, Seattle, Washington and the University of California, Davis, California. Personnel responsible for this work include:

Boeing Military Airplanes:
D. Gangsaas, responsible manager
T. M. Richardson, program manager
G. C. Cohen, principal investigator

University of California:
Dr. K. N. Levitt, chief researcher
Jing Pan, PhD candidate

1.0 INTRODUCTION

Formal hardware verification involves using mechanized theorem-proving techniques to verify that the design of a system satisfies its specification. Because exhaustive simulation is often too time consuming, and because simulation that is non-exhaustive might miss cases that are incorrect, there is increasing interest in using a formal approach to reason about hardware designs. This report describes work in progress on verifying a floating-point coprocessor based on the MC68881 (ref. 1), (ref. 2)\(^1\). The coprocessor consists of a bus interface unit (BIU) which communicates with the CPU, and an arithmetic processing unit (APU).

There has been significant interest in formal verification in recent years (ref. 3), (ref. 4), (ref. 5), (ref. 6), (ref. 7), (ref. 8), (ref. 9), (ref. 10). Formal proofs of complex systems are not trivial, requiring significant machine time and human effort. Perhaps the best known verification effort is that of the VIPER microprocessor (ref. 3), (ref. 4). VIPER is the first microprocessor intended for commercial distribution where a formal verification has been attempted.

Recent work (ref. 11), (ref. 12) has shown that the verification of microprocessors can be simplified through insertion of intermediate levels of abstraction between the instruction set and the electronic block model (EBM); the EBM is, generally, the lowest level in the hierarchy and, logically, represents the object being verified. Through these appropriate intermediate levels, long and complex proofs are replaced by many more simple proofs. Furthermore, each level is a self-contained abstraction that has meaning in the explanation of the system. That is, the overall approach of abstraction reflects the way complex microprocessors are designed. In (ref. 10), microprocessors with four levels of abstraction are considered. The macro level reflects the programmer's view of instruction execution. At the micro level, an instruction is interpreted by executing a sequence of microinstructions. The phase level description decomposes the interpretation of a single microinstruction into the parallel execution of a set of elementary operations. The lowest level is the electronic block model, where a number of blocks such as the registers, the ALU and the microROM are connected together. It is generally accepted that the correctness of the EBM can be established by simulation.

This report concentrates on two tasks: the first involves the formal composition of three interpreters (the CPU service, the BIU top level, and the APU top-level interpreter), the composition producing the floating-point coprocessor (FPC). The CPU service interpreter is that part of the CPU

\(^1\)The coprocessor was designed based on the information contained in the MC68881 user's manual
specification concerned with communication with the BIU. The second task is concerned with the composition of the CPU and the FPC to form a more abstract view of a computer system, consisting of both the CPU and FPC. This composition would be verified with respect to a specification of a single abstract interpreter that provides both integer and floating-point instructions.

There are five sections to this report. Section two briefly describes the basic architecture of the floating-point coprocessor being verified, emphasising the communication and synchronization functions; section three presents a methodology for verifying the composition of three interacting interpreters, the goal being the verification of the coprocessor; section four discusses our approach to the verification of the CPU-FPC combination.
2.0 THE FLOATING-POINT COPROCESSOR ARCHITECTURE

We now present the design of a floating-point coprocessor (FPC) that is a simplification of the MC68881. Our coprocessor is designed to interface with a CPU to provide a logical extension to the CPU's integer data processing capabilities. The assembly language programmer can view the FPC registers as though they are resident in the CPU. Thus, the CPU and FPC pair appears to the programmer to be one processor that supports both floating-point and integer operations. That the floating-point and integer operations are processed by different processors is an implementation detail to the programmer. Moreover, the coprocessor interface allows the FP instructions to execute concurrently with the CPU instructions to improve efficiency, but this, too, is an implementation detail.

2.1 THE HARDWARE OVERVIEW

The coprocessor is internally divided into two processing elements: the bus interface unit (BIU) and the arithmetic processing unit (APU) (see fig. 2.1-1). Though the BIU monitors the state of the APU, it operates independently of the APU. The APU operates on the opcode and operands that the BIU passes to it. In return, the APU reports its internal state to the BIU. The BIU contains the coprocessor interface registers (CIRs) and status flags. The CIR register select and acknowledgement control logic are also contained in the BIU. The coprocessor interface implements a protocol that controls the access of these registers by the CPU and the APU. Since the bus is asynchronous, the FPC need not run at the same clock speed as the CPU.

The APU executes all the floating-point instructions. The floating-point data, control and status registers are located inside the APU. In addition to these registers, the APU contains an arithmetic unit used for both mantissa and exponent calculations, and a barrel shifter.

2.2 THE COMMUNICATION PROTOCOL

As mentioned in the last section, the FPC contains a number of coprocessor interface registers (CIRs) which are addressed by the CPU in the same manner as memory is addressed. When the CPU fetches a coprocessor instruction, the CPU writes the instruction to the command CIR and reads the response CIR. In this response, the BIU encodes requests for any additional service required by the FPC. Data values read by the CPU from the FPC response CIR are referred to as
"primitives". The response has one of the following meanings:

a. The FPC is busy. The CPU then checks for interrupts, processes them, and queries the FPC again. In this case, the CPU will not execute the next instruction in the program.

b. There is a FPC service request. For example, this request might be to evaluate the effective address and deliver data from the CPU data registers/memory to the FPC.

c. The CPU is not needed. Communication is terminated, and the CPU is free to execute the next instruction.

There are four CIRs that reside inside the BIU. The read-only/write-only designations apply to the CPU's access to these registers.

a. Response CIR. This read-only register is used to communicate service requests from the FPC to the CPU.

b. Command CIR. This write-only register is used by the CPU to initiate a dialog for a coprocessor instruction. When the FPC detects a write to this CIR, the data value is latched from
the data bus.

c. Condition CIR. This write-only register is used by the CPU to initiate the dialog for a
conditional coprocessor instruction.

d. Operand CIR. This read/write register is used by the CPU to transfer data to and from the
FPC.

Currently we do not have exception-handling capabilities built into the coprocessor. We plan
to consider this feature in the future. Several additional CIRs will be needed to accommodate
exception-handling capabilities.

2.3 THE INSTRUCTION SET

The FPC instructions can be separated into three groups:

a. Data movement instructions. The FLD and FSTR instructions are used to transfer data between
the floating-point data registers and the main memory or the CPU data registers.

b. Arithmetic operation instructions. One or two operands are specified. The results is always
stored into one of the internal FPC data registers. At most one operand may come from
outside (the CPU registers or the memory).

c. System control instructions.

2.4 CONCURRENCY AND SYNCHRONIZATION

Since one FPC instruction usually takes much more time to complete than a CPU instruction, it
is desirable for both the CPU and the FPC to be executing instructions simultaneously. When the
CPU encounters an FPC instruction, it (1) busy-waits until the FPC becomes idle (although it can
service interrupts), (2) causes the FPC to begin the instruction, and then (3) immediately services
the next instruction.

The concurrency between the CPU and the FPC must be implemented to maintain a programming
model based on sequential instruction execution. There are two possible ways the CPU and the
FPC may interfere with one another; they must both be disallowed:
a. The CPU cannot start another FPC instruction if the FPC is still busy executing the previous instruction.

b. The CPU cannot reference a memory location that is being referenced by the previous (but still executing) FPC instruction.

The first coordination problem is solved by the CPU's busy wait feature, while the second one is solved by the assumption underlying the FPC instruction set. There is no arithmetic instruction that can store the result to the memory or the CPU registers. The only way to move data from the FPC to the outside world is through the FSTR instruction, which finishes execution as soon as the communication between the CPU and the FPC is finished. Therefore the CPU guarantees that all programs will produce the same result as if there were only one processor instead of two.
3.0 VERIFYING THE FPC TOP LEVEL FROM THE THREE COMMUNICATING UNITS

As we recall from the previous section, one floating-point instruction is accomplished by the cooperative effort of three units: the CPU, the BIU and the APU. The verification of the communication among the three units is the main focus of this section.

The FPC top-level interpreter is implemented by three interpreters: the BIU top-level interpreter, the APU top-level interpreter and the CPU service interpreter (fig. 3.1-1). Each interpreter has a separate specification, making it possible to reason independently about each interpreter. The specifications are then composed in order to reason about their interaction. Thus, a proof that each interpreter is implemented correctly can be carried out independently of the others.

Since each interpreter is specified independently, we do not assume there is a master clock shared by all the units. Each unit has its own clock. Moreover, for each unit, interpreters on different abstraction levels also have different time scales. All communication between the units is assumed to be performed asynchronously. The busy waiting mechanism used by Joyce (ref. 7) was used to specify and verify the asynchronous interaction among the units.

3.1 HIERARCHICAL DECOMPOSITION

Windley (ref. 10) describes a hierarchical decomposition of a computer system as a sequence of interpreters:

\[ S \Rightarrow B_1 \Rightarrow \ldots \Rightarrow B_n \]

where S is the structural description, and \( B_1 \) through \( B_n \) represent increasingly abstract specification of the system. Generalizing this principle leads to a tree structure or possibly a directed, acyclic graph, if the computer system structure is a collection of independently operating units. In the case of a tree, at the root of the tree we have the top-level specification for the whole system. The leaves of the tree correspond to the structural specifications of the physical units. The nodes in the middle represent various intermediate abstract specifications for the units.

By applying the above generalized decomposition principle to the floating-point coprocessor, we obtain the decomposition illustrated in fig. 3.1-1. This model extends the one Windley adapted for his microprocessor by allowing an interpreter to be implemented by more than one lower-level interpreter. Therefore, besides the vertical interaction between the lower-level and the higher-level in-
interpreters, there is horizontal interaction between the lower-level interpreters. The verification that the composition of several lower-level interpreters implements a higher-level interpreter presents a problem not previously formalized for hardware verification, and is addressed here.

Figure 3.1-1: An Extended Hierarchy of Interpreters for the FPC

We adapted a model for describing the interpreters at various abstraction levels. An interpreter is a process organized as a state transition system defining the state $s$, the environment $e$, and a set of transition functions $J$ that relate the state at time $t+1$ to the state and the environment at time $t$. In our model, the environment is used only for input; output to the environment is modeled as part of the state. Each level in the interpreter hierarchy has its own state, environment and time scale. A mapping function is used to relate the states, environments and the time scale of vertically adjacent interpreters.
3.2 THE FOUR-PHASE HANDSHAKING PROTOCOL

The FPC executes two different bus cycles, according to the direction of the transfer. They are the asynchronous read and asynchronous write bus cycles. The four-phase handshaking protocol is used to implement these two types of bus cycles. For the read cycle, the FPC detects the start of an asynchronous read cycle when the read request line is asserted by the CPU. The FPC puts its data value on the bus and asserts the acknowledgement line (dtack). The acknowledgement remains asserted until the read request line is lowered by the CPU to signify the end of the read cycle. The BIU then lowers the acknowledgement line (fig. 3.2-1).

![Diagram](#)

Figure 3.2-1: The 4-Phase Protocol Time Diagram

Fig. 3.2-1 represents the actual signal exchange in the implementation of the four-phase handshaking protocol. The implementation of this protocol is represented in the lower levels of the interpreter hierarchy (e.g., CPU 4-phase). We would like, however, to define a more abstract view of message passing between the CPU and the BIU where the handshaking detail is hidden. This more abstract view of communication can then be used in the next higher level, that is, in reasoning about the interaction between the CPU and the BIU during the execution of an FPC instruction.

The definition cir_read_write states that the read or write cycle will be successfully accomplished in one time unit on the more abstract (higher-level) time scale. In addition, proper signals such as
new_instr and operand_ready are raised so that the BIU will know which CIR the data is latched into. Since the data transmitted on the data bus are of type wordn (abstract type of a word of length n), type conversion is needed in both reading and writing cycles. When an instruction is written to the command CIR, signal new_instr is raised. Similarly, operand_ready will be raised if the data is written into the output operand CIR.

```
cir_read_write rep address read write datain dataout
    command response operand_in operand_out condition
    control new_instr operand_ready =

\[
\forall t.
\begin{align*}
(read t) \Rightarrow & \text{ read cycle} \\
((address t = 1) \Rightarrow ((datain(t+1) = (numtow rep (response t))) \land
 & (new_instr t) \land
 & (operand_ready t))) \lor
((datain(t+1) = (fptow rep (operand_in t))) \land
 & (new_instr t) \land
 & (operand_ready t)))
\end{align*}
\]

\[
(write t) \Rightarrow \text{ write cycle} \\
((address t = 0) \Rightarrow (((command(t+1)) = (wtonum rep (dataout t))) \land
 & (new_instr t = T)) \lor
((operand_out(t+1) = (wtofp rep (dataout t))) \land
 & (operand_ready t = F) \land
 & (operand_ready (t+1) = T)))
\]

Xidle cycle %

```

To prove that the implementation of the four-phase handshaking protocol actually implements the more abstract description cir_read_write, a temporal abstraction from the lower-level time scale to the upper-level time scale has to be used (ref. 13). Temporal abstraction deals with the sequential or time-dependent behavior of a device viewed at different "grains" of discrete time.

### 3.3 SPECIFICATION OF THE THREE INTERPRETERS

This section describes the specification of the top-level interpreters of CPU service, BIU and APU. The state tuple and the environment tuple for each of the interpreters are listed in the following
two tables:

<table>
<thead>
<tr>
<th>Interpreters</th>
<th>state</th>
</tr>
</thead>
<tbody>
<tr>
<td>CPU_Service</td>
<td>(c_ac,c_reg,mem,dataout,address,read,write,cpu_state)</td>
</tr>
<tr>
<td>BIU</td>
<td>(response,operand_out,decode_reg,resp_ready,f_ac,biu_state,start)</td>
</tr>
<tr>
<td>APU</td>
<td>(f_ac,f_reg,cw,sw,done)</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Interpreters</th>
<th>environment</th>
</tr>
</thead>
<tbody>
<tr>
<td>CPU_Service</td>
<td>(resp_ready,datain,ir)</td>
</tr>
<tr>
<td>BIU</td>
<td>(command,condition,control,operand_in,done,new_instr,operand_ready)</td>
</tr>
<tr>
<td>APU</td>
<td>(start,decode_reg)</td>
</tr>
</tbody>
</table>

Although the data bus physically is one bi-directional bus, we chose to represent it as two unidirectional buses: datain and dataout. Fig. 3.3-1 depicts the connection between the CPU and BIU. Instructions and data fetched from the memory are written by the CPU to the command and output operand CIR through dataout. Similarly, response and data fetched from the FPC accumulator are sent by the BIU through the datain bus. The CPU and FPC accumulator and registers are denoted as c_ac, c_reg, f_ac and f_reg, respectively.

![Diagram](image)

Figure 3.3-1: The States and Environment
### 3.3.1 Specifying the CPU Service Interpreter

The CPU service interpreter is the part of the CPU specification that is responsible for communicating with the BIU in order to execute a floating-point instruction. Since the CIRs reside in the BIU, reading from or writing to any CIR by the CPU is accomplished by the four-phase handshaking protocol.

The CPU service interpreter specification is organized as a state machine that has six states. In state 0, the CPU starts the communication by sending out the current FPC instruction to the BIU. The CPU then "busy waits" in state 1 for the BIU to put the proper service request in the response CIR. In state 3, the CPU reads the response CIR, and enters the appropriate state to provide the requested service. If the response is a null primitive, then the CPU is no longer needed and, therefore, is free to execute other instructions; if the response is a read primitive (for FLD instruction), then the CPU fetches the data from the memory, raises the write request line, puts the data on the data bus, and goes back to state 0; if the response is a write primitive (for the FSTR instruction), then the CPU waits until the data is ready in the operand CIR, retrieves it from the data bus, and stores it to the memory.

The function `cpu_service_state` determines the new state for the CPU service interpreter from the current state and the environment by the current value of the state counter `cpu_state`.

```plaintext
cpu_service_state n rep cpu_state =
  (+ ((cpu_state = 0) ⇒ (cpu_begin n rep) |
  (cpu_state = 1) ⇒ (cpu_wait_for_response n rep) |
  (cpu_state = 2) ⇒ (cpu_wait_4phase n rep) |
  (cpu_state = 3) ⇒ (cpu_read_response n rep) |
  (cpu_state = 4) ⇒ (cpu_wait_read n rep) |
  (cpu_put_data n rep))
```

There are four parameters for each state transition function. The second parameter `rep` is the representation parameter for abstract data types such as `wordn` and `memory`. A number of abstract operations are defined on the abstract data types. For example, the function `wordn` converts a `wordn` typed object to type `number`. The third parameter is the state tuple, and the last one is the environment tuple. The following is the definition of `cpu_begin` where the CPU sends out a new instruction to the BIU. The CPU raises the write request line and puts the instruction on the data bus.
Note a few details regarding state 1, where the CPU waits for the BIU to finish putting the appropriate response primitive into the response CIR. Since the CPU and the FPC do not share the same master clock, the FPC will have to raise a response ready line (resp_ready) to inform the CPU when the response is ready. The MC68881 does not use the technique of a resp_ready line. Instead, a so-called "synchronous" read cycle is used to read the response CIR. This "synchronous" read cycle relates the bus cycle timing directly to the FPC clock to allow the proper response primitive to be prepared.

The top-level specification of CPU service relates the state at time t+1 to the state and environment at t by the next state function:

```plaintext
cpu_service n rep (c_ac, c_reg, mem, ir, dataout, address, read, write, 
cpu_state) (resp_ready, datain) = 
  (c_ac, c_reg, mem, ir, (numtow rep ir), 0, F, T, 1)
```

3.3.2 SPECIFYING THE BIU TOP-LEVEL

In order to allow a FPC instruction to start executing, the BIU communicates with the CPU to obtain the necessary information, and to inform the APU to start processing in the case of an arithmetic instruction. There are four states for the BIU top-level state machine. In state 0, the BIU is idle and waits for the next instruction to be sent over by the CPU. In state 1, the BIU decodes the current instruction in the command CIR and determines whether the CPU is needed to transfer data. If a transfer is required, a read or write primitive is placed into the response CIR. Otherwise, the null primitive is issued to inform the CPU of the termination of the communication for arithmetic instructions. Further, the APU is started when the instruction is an arithmetic instruction. If the instruction is FLD, the BIU waits for the CPU to place data in the operand CIR.
and then the BIU transfers the data to the FPC accumulator. If the instruction is FSTR, the BIU fetches data from the FPC accumulator and stores it in the operand CIR, making it available for the CPU. For arithmetic instructions, the BIU waits till the APU finishes executing.

\[
\begin{align*}
\text{bin_top_state} & = \text{bin_state} = \\
& (\text{bin_state} = 0) \Rightarrow (\text{bin_idle}) \\
& (\text{bin_state} = 1) \Rightarrow (\text{biu_decode}) \\
& (\text{bin_state} = 2) \Rightarrow (\text{bin_wait_op}) \\
& (\text{bin_state} = 3) \Rightarrow (\text{biu_fld}) \\
& (\text{bin_wait_apu})
\end{align*}
\]

In order to compose the CPU, the BIU and the APU interpreter, the three interpreters have to be expressed with respect to a common time scale. We chose the cpu_service clock rate as the common clock rate. Therefore, the behavior of biu_top and apu_top must be described in terms of the clock rate of cpu_service. We chose to use existential quantification to describe the BIU top-level behavior. More specifically, the specification states that there exists some future time \( t' \) such that the BIU finishes executing. If the clock of apu_top is faster or of the same speed as the clock of cpu_service, \( t' \) will be equal to \( t+1 \). However, if the apu_top clock is slower, \( t' \) will be bigger than \( t+1 \).

The following definition is the APU top-level behavior from the CPU's point of view. The interpreter for the BIU top-level relates the state tuple at time \( t+1 \) or \( t' \) to the state and environment tuple at time \( t \), depending on whether the BIU is waiting for the CPU or is doing some work required for the current FPC instruction. For example, at state 1, if the FPC instruction arrives at CPU time \( t \), then at CPU time \( t' \) the instruction will be decoded and the proper response is sent. Further, \( t' \) is the first time that the response is ready (First \( (t, t') \) resp_ready), and the start signal to the APU will remain stably low from \( t \) to \( t' \) (Stable \( (\text{start}, F, t, t') \)).
biu_top_cpu n rep (response, operand_out, decode_reg, resp_ready, f_ac, biu_state, start)
    (command, condition, control, operand_in, done, new_instr, operand_ready)
    =
    V (t : num). ∃ (t' : num). ((t+1)<=t') ∧
    (let state_tuple = (state_tuple_biu t) and
    state_tuple1 = (state_tuple_biu (t+1)) and
    env_tuple = (env_tuple_biu t) and
    state_tuple' = (state_tuple_biu t') in

    (((biu_state t = 0) ∨ (biu_state t = 2)) ⇒
    (state_tuple1 = biu_top_state n rep (biu_state t)
    state_tuple env_tuple)) |
    (biu_state t = 1) ⇒
    ((First (t, t') (resp_ready)) ∧
    (Stable (start, F, t, t')) ∧
    (state_tuple' = (bin_decode n rep state_tuple env_tuple))))) |
    (biu_state t = 3) ⇒
    (((operand_ready t)) ⇒
    (state_tuple1 = (response t, operand_out t, decode_reg t,
    resp_ready t, f_ac t, 3, start t)) |
    ((Stable (start, F, t, t')) ∧
    (state_tuple' = (response t, operand_out t, decode_reg t,
    resp_ready t, operand_out t, 0, start t)))}) |
    (state_tuple' = (bin_top_state n rep (biu_state t)
    state_tuple env_tuple))))

3.3.3 SPECIFYING THE APU TOP-LEVEL

The APU top-level interpreter describes the APU behavior with respect to each floating-point arithmetic instruction. The state on the APU top-level does not contain the instruction register, the CPU accumulator, the CPU registers and the memory. Instead the APU gets the current instruction from the decoder register that resides inside the APU. For example, the specification APU_FADD asserts that the content of the FPC accumulator is added to the content of a designated FPC register, and the result is stored in the accumulator.
NextState_apu determines the new state for the APU top-level interpreter from the current state and environment according to the opcode of the current instruction stored in the decoder register. The execution of load and store instructions do not involve the APU. For this discussion, we are only concerned with four arithmetic instructions, that is addition, subtraction, multiplication and division.

```plaintext
NextState_apu n rep opcode =
  (opcode = 2) ⇒ (APU_FADD n rep) |
  (opcode = 3) ⇒ (APU_FSUB n rep) |
  (opcode = 4) ⇒ (APU_FNUL n rep) |
  (APU_FDIV n rep))
```

Similar to biu_top_cpu, apu_top_cpu specifies the APU top-level behavior from the CPU's point of view. It states that if the start signal has not arrived, the APU will remain idle. If the APU starts to execute at CPU time \( t \), however, then there exists some future CPU time \( t' \) that the APU will finish the execution of the instruction.

```plaintext
apu_top_cpu n rep (f_ac, f_reg, cw, sw, done)
  (start, decode_reg) =
  ∀ t . (¬start t) ⇒
  ((f_ac(t+1), f_reg(t+1), cw(t+1), sw(t+1), done(t+1)) =
   apu_idle n rep (f_ac t, f_reg t, cw t, sw t, done t)
   (start t, decode_reg t)) |
  (∃ t' . (t ≤ t') ∧
   (First (t, t') (done)) ∧
   ((f_ac t', f_reg t', cw t', sw t', done t') =
    NextState_apu n rep (Opc n (decode_reg t))
   (f_ac t, f_reg t, cw t, sw t, done t)
   (start t, decode_reg t)))
```
3.4 VERIFYING THE FPC TOP-LEVEL

This section describes the methodology used to verify that the cooperative effort of the three interpreters implements the FPC top-level specification. The key to this proof is the asynchronous communication among the three interpreters.

3.4.1 SPECIFYING THE FPC TOP-LEVEL

The function performed by each FPC instruction is not accomplished by the coprocessor alone, but requires interaction with the CPU. Hence, the state visible at this level includes the FPC registers plus the CPU registers and the memory contained in the CPU service interpreter state. The CPU registers and the instruction register do not reside inside the FPC, nor does the coprocessor directly reference the memory, but the FPC top-level interpreter reflects the assembly language programmer's point of view of floating-point instruction execution and treats the FPC as a single unit. For example, from the programmer's point of view, the current FPC instruction being executed is in the instruction register, and the FLD and FSTR instructions directly load from and store to the memory.

The specification for the FPC instruction FLD at the FPC top-level is as follows, where \( c_{ac} \), \( c_{reg} \), mem and ir are the CPU accumulator, the CPU data registers, the main memory and the instruction register, respectively. The FLD instruction fetches data from the main memory and stores it to the FPC accumulator. Function \((\text{Addr n ir})\) returns the memory address of the operand that is fetched.

\[
\text{FLD n rep (f_ac, f_reg, c_ac, c_reg, mem) (ir) = }\\
\text{let data = fetch rep mem (Addr n ir) in }\\
\text{(((wtofp rep) data), f_reg, c_ac, c_reg, mem)}
\]

The interpreter for the FPC top-level is expressed as a predicate relating the value of the state tuple at time \( t' \) to the value of the state tuple at time \( t \) according to the function \( \text{NextState}_{fpc} \). The reason that each instruction is specified to finish at some time \( t' \) instead of \( t+1 \) is that the behavior of the FPC is specified from the CPU's point of view. This specification will be used later to compose the CPU top-level specification and the FPC top-level specification to form a complete computer system.
3.4.2 WAITING STATES

Sometimes the APU top-level interpreter and the CPU service interpreter must wait until some signal becomes high. During these waiting periods, the state tuple remains unchanged. For example, for the CPU service interpreter, its state machine waits in state 1 until the signal resp_ready becomes high. Using induction on the length of the wait period, we can prove theorem wait_cpu stating that the state counter cpu_state (which is an element of the cpu_service state tuple) remains stable while the CPU is waiting in state 1 for the signal resp_ready.

There are a number of theorems in this form. For example, theorem wait_cpu2 states that the memory and the instruction register remain stable until the response has arrived (because the CPU has not been freed from its floating-point execution duty at this point). Similarly, wait_apu guarantees that the FPC accumulator and registers will remain stable until the signal start from the BIU arrives. Theorems such as this will be used in the next section to reason about the interaction of the three implementing interpreters to prove the FPC top-level interpreter.

### 3.4.3 VERIFYING THE FLD INSTRUCTION

To verify the FPC top-level interpreter, the interaction of the three implementing interpreters must be formalized. Although the FPC top-level interpreter is defined in terms of state transitions that represent the execution of single instructions, each FPC transition represents some unspecified
number of transitions by the lower-level interpreters. An example of this is shown in the following theorem, FLD_Correct.

\[
\text{FLD\_Correct} = \\
\text{∀ response operand\_out decode\_reg biu\_state start command} \\
\text{condition control operand\_in done new\_instr operand\_ready} \\
\text{resp\_ready f\_ac f\_reg cw sw c\_ac c\_reg mem ir cpu\_state} \\
\text{address read write datain dataout n.} \\
(\text{biu\_top\_cpu n rep state\_tuple\_biu env\_tuple\_biu}) \land \\
(\text{apu\_top\_cpu n rep state\_tuple\_apu env\_tuple\_apu}) \land \\
(\text{cpu\_service n rep state\_tuple\_cpu\_service env\_tuple\_cpu\_service}) \land \\
(\text{cir\_read\_write rep} \\
\text{address read write datain dataout command} \\
\text{response operand\_in operand\_out condition control} \\
\text{new\_instr operand\_ready}) \implies \\
(\forall t. \\
(\text{Opn n(ir t) = 0}) \land \%FLD\% \\
\text{\_start t} \land \\
(\text{biu\_state t = 0}) \land \\
(\text{cpu\_state t = 0}) \implies \\
(\exists t'. \\
(f\_ac t', f\_reg t') = \\
\text{FPC\_state}(\text{FLD n rep(f\_ac t, f\_reg t, c\_ac t, c\_reg t, mem t, ir t))))
\]

Theorem FLD\_Correct states that the FLD instruction is correctly implemented by the three interacting units: the CPU service, the BIU and the APU. More formally, the definitions of the CPU service, BIU, APU and the correctness of the four-phase protocol imply that for any time t, where the current instruction is FLD and each of the three units are in their initial states, the effect of running the three lower-level interpreters together is the same as that of running the top-level FPC interpreter. Function FPC\_state is used to filter out some elements from the state tuple that might be changed by the CPU after the CPU is freed from its floating-point activity. These elements are the CPU accumulator and registers, the memory, and the instruction register. The same is true for the arithmetic instructions. However, for the FSTR instruction, the entire state will be used since the CPU will not be free until the FSTR is finished execution.

To illustrate the verification technique, we examine the interaction between the three units for the FLD instruction. At time t, the BIU and APU are idle and cpu\_service initiates the communication
by sending out the current FPC instruction to the BIU. More specifically, the CPU raises the write request line and places the instruction on the data bus (state transition function cpu_begin). The correctness property of the four-phase handshaking protocol (cir_read_write) ensures that the instruction is delivered to the command CIR and the signal new_instr is raised.

At time t+1 the state machine of the CPU service interpreter is in state 1 and waiting for the response ready signal resp_ready from the BIU. At time t+2 the BIU discovers that a new instruction is placed in its command CIR; it then decodes the instruction and puts a proper response primitive into the response CIR. In this case, the response is a read primitive. Since the BIU operates on a different clock, the decoding will be done at time t', with t' bigger than t (state transition function biu_decode).

During the interval t+2 to t', the CPU and the APU are idle. The waiting theorems described in the previous section ensure that the state tuples of the CPU service and the APU remain unchanged. The CPU detects that the proper response is ready at t', and enters state 2 to wait for the response to be put on the databus. The CPU reads the response from the databus at t'+2 and realizes that data needs to be fetched from the memory. Thus, the CPU fetches the data, raises the write request line and puts the data on the databus (cpu_read_response). From now on, the CPU is no longer needed, and is free to execute other CPU instructions. The four-phase protocol ensures that the data will be put into the operand CIR. At time t'+4 the BIU stores the data to the accumulator and the whole operation is finished (biu_fld). During the entire process, the APU remains idle. A more detailed view of the communication among the three interpreters is illustrated in fig. 3.4-1.

### 3.4.4 VERIFYING THE FPC TOP-LEVEL INTERPRETER

Theorems like those above are proved for every FPC instruction (currently six of them). These theorems are used to establish a theorem stating that the three top-level interpreters of CPU service, BIU and APU imply the FPC top-level. The initial condition is more complicated in this proof. Usually when proving the correctness of a microprocessor, for instance from micro level to macro level, the initial condition will be that the microprogram counter is zero. Here a function Initial_State is defined to include the initial conditions for all three components.

\quad (\text{start,new\_instr,resp\_ready,read,biu\_state,cpu\_state})
\]
4.0 COMBINING THE CPU AND THE FPC

With the inclusion of the FPC, the system provides an instruction set which contains both the CPU instruction set and the FPC instruction set. At the abstraction level of the assembly language programmer, the system appears as a single unit. Furthermore, at this level of abstraction, the instructions appear to be executed in a sequential manner. However, the underlying implementation of instructions is concurrent. This sequential execution of instructions is "equivalent" to the underlying concurrent execution only in the sense that the final result of the program will be identical. This section discusses our methodology for specifying and verifying the computer system consisting of the CPU and the FPC as shown in fig. 4.0-1. More specifically, we are going to discuss the approach to abstract the FPC top-level to the concurrent top-level and subsequently to the sequential top-level.

![Hierarchical Decomposition of the CPU-FPC System](image)

4.1 SPECIFYING THE SEQUENTIAL TOP-LEVEL INTERPRETER

The sequential top-level interpreter (shown in outline form in Sequential_Top_Level) reflects the assembly language programmer's view of sequential execution. The functions FPC.NextState and CPU.NextState execute the current FPC or CPU instruction pointed to by the program counter.
\[
\text{Sequential\_Top\_Level state env = }
\]
\[
\vdash \forall \text{ time } t.
\]
\[
\text{if current instr is a FPC instr } \Rightarrow 
\]
\[
\text{state}(t+1) = \text{FPC\_NextState (state } t \text{) (env } t \text{)} \cup 
\]
\[
\text{state}(t+1) = \text{CPU\_NextState (state } t \text{) (env } t \text{)} 
\]

The total state at this level state can be partitioned into three disjoint sets: (1) \text{cpu.s}, which includes the CPU data registers and the memory; (2) \text{fpc.s}, which includes the FPC data registers; and (3) \text{joint.s}, which has the program counter. If the current function is FSTR, the function \text{FPC\_NextState} modifies the total state. However, if the current instruction is a FPC instruction other than FSTR, then \text{FPC\_NextState} only modifies \text{fpc.s} and \text{joint.s}. Similarly, the function \text{CPU\_NextState} only modifies \text{cpu.s} and \text{joint.s}, but not \text{fpc.s}. Note that \text{cpu.s} is not the state at the CPU top-level. The same applies for \text{fpc.s}. This will be discussed in the next section.

At the concurrent top-level, each clock tick represents the start of a new instruction. A CPU instruction only needs one clock cycle to complete, while a FPC instruction may need more than one cycle. In addition, a FPC instruction cannot be started unless the FPC has finished the previous instruction. The state and the environment at this level is the same as those at the sequential top-level.

\[
\text{Concurrent\_Top\_Level state env = }
\]
\[
\vdash \forall \text{ time } t.
\]
\[
\text{if the current instr is of FPC type } \Rightarrow 
\]
\[
(\exists \text{ c. at } t+c, \text{ the FPC instr will be completed } \land 
\]
\[
\forall t', (0 < t' < c \Rightarrow 
\]
\[
\text{the instr at } t+t' \text{ is not a FPC instr!} 
\]
\[
\text{at } t+1, \text{ the CPU instr will be completed) } 
\]

We need to prove the following sequential top-level correctness statement (with the correct abstraction function).

\[
\text{Concurrent\_Top\_Level } \land \text{ Non\_Interference } \Rightarrow \text{ Sequential\_Top\_Level } 
\]

The non-interference property has the following four aspects:
a. The state of the CPU cpu_s and the FPC fpc_s are disjoint.

b. The CPU never modifies the FPC state.

c. The FPC never modifies the CPU state except using FSTR instruction.

d. A FPC instruction is never started unless the FPC has finished executing the previous instruction.

Conditions (a) to (c) are implicitly provided by the nature of the instruction set, and are modeled in Non-Interference in the above correctness statement. The fourth condition is guaranteed by the implementation and modeled in the specification of the concurrent top-level interpreter.

4.2 THE ABSTRACTION FROM THE CONCURRENT LEVEL TO THE SEQUENTIAL LEVEL

Suppose the sequential execution flow of an instruction stream is "F₁C₁C₂C₃F₂C₃F₄C₄C₅C₆", where F's and C's represent FPC and CPU instructions, respectively. The sequential and concurrent execution sequence of the above instruction stream is depicted in fig. 4.2-1. The dotted line indicates the mapping points of the abstraction, which will be discussed later. The instruction labels marked above the line are the starting time of the corresponding instructions, while the labels below the line represent the finishing time. For example, on the concurrent level, instruction F₁ starts at time 0, finishes at time 3.

Fig. 4.2-2 shows the sequential top-level state and the concurrent top-level state for the above instruction stream at each clock tick. The CPU state cpu_s on both levels are always the same at each clock tick. However, at some point the FPC state fpc_s on the concurrent level is different from fpc_s on the sequential level. For instance, at time 2 the total state on the sequential level equals the CPU state modified by C₁, the FPC state modified by instruction F₁, and the incremented programmer counter (the first table). At the corresponding time the total state on the concurrent level equals the CPU state modified by C₁, the FPC state at time 1 and the incremented programmer counter (the second table). In this particular example, the total state on the sequential level and the total state on the concurrent level are equivalent at time 3, 4, 5, 7 and 10; while at all other points the total states on the two levels are different.

because of branching instructions, the program and its sequential execution sequence might be different
More formally, assume the instruction stream is:

\[ F, C_1, C_2, \ldots, C_n, F' \]

Since CPU instructions \( C_1 \) to \( C_n \) do not interfere with \( F \), any one of the following execution sequences will have the same result as the above. The only requirement is that \( F \) must be executed before \( F' \). Depending on the instruction type of \( F \) and how fast each instruction is executed, the concurrent top-level interpreter will specify one of the following sequences:

\[ F, C_1, C_2, C_3, \ldots, C_n, F' \]
\[ C_1, F, C_2, C_3, \ldots, C_n, F' \]
\[ C_1, C_2, F, C_3, \ldots, C_n, F' \]

Suppose \( F \) does not finish until \( C_i \) starts. This is equivalent to:

\[ C_1, C_2, \ldots, C_{i-1}, F, C_i, \ldots, C_n, F' \]

Further assume the instruction stream starts at time 0. Then the FPC state on the concurrent level from time 0 to time \( i-1 \) is always equivalent to the FPC state at time 0 on the sequential level, since \( F \) does not finish executing until time \( i \). However, from time \( i \) to \( n \), the total state

</tbody>
</table>
on the two levels are identical. Although the exact time that F finishes is unknown, F will finish
before F’ starts. Therefore at time n+1 (the time F’ starts), the total state on the sequential level
is guaranteed to be identical to the total state on the concurrent level.

Instead of looking at the state after the execution of each instruction, a “chunk” of instructions is
examined. Each “chunk” is defined by a sequence of the form FC*, denoting one floating-point
instruction followed by zero or many CPU instructions. The start of a “chunk” is a floating-
point instruction, and the termination is the last CPU instruction that precedes a floating-point
instruction. In the example presented in fig. 4.2-1, the “chunks” are “F1C1C2C3”, “F2”, “F3C4”,
“F4C5C6”. At the end of each “chunk”, the states on the two levels are always identical. Those
points, therefore, become the mapping points between the concurrent top-level and the sequential
top-level.

4.3 VERIFYING THE CONCURRENT TOP-LEVEL

As depicted in fig. 4.0-1, the concurrent top-level interpreter is implied by two lower-level inter-
preters: the CPU top-level and the FPC top-level interpreters. The synchronization between the
CPU and the FPC is specified by both the CPU and the FPC top-level interpreters.

The CPU top-level interpreter determines if the current instruction is a FPC instruction. If it is,
then the CPU will synchronize with the FPC by waiting until the FPC is idle. Otherwise, the
interpreter relates the state at t+1 to the state and environment at t through the CPU instruction
selected according to the current program counter: At this level, the state has part of the concurrent
top-level state which does not concern the FPC, for example the CPU registers, the memory, the
program counter, plus the busy line emitted by the FPC.

```
CPU_Top_Level state_cpu env_cpu =
true ∀ time t.
  if the current instr is FPC type ⇒
    (if FPC is busy ⇒
     state_cpu(t+1) = wait until FPC is idle |
     state_cpu(t+1) = finish the communication |
     state_cpu(t+1) =
     (Selected CPU instr) (state_cpu t) (env t)
```

The concurrent top-level correctness statement is as follows:

28
Usually, when proving an implementation (lower-level interpreter) implies a specification (an upper-level interpreter), a temporal abstraction is defined from the lower-level time scale to the upper-level time scale (fig. 4.3-1). However, in this case there are two units on the lower level, each with its own independent time scale. One way to solve this problem is to map the FPC time to the CPU time scale.

For example, in fig. 4.3-1, $F_1$ is actually completed by the FPC before the CPU completes the execution of $C_2$. However, since the clock ticks on the concurrent top-level only represent the starting time of each instruction, $F_1$ is not considered to be finished until $C_3$ starts executing, which is the same time $C_2$ finishes. The notation $*F_1$ denotes the communication between the CPU and the FPC for the instruction $F_1$. The waiting of the CPU for the FPC to finish execution is signified by "w.....", and the FPC's idle period is signified by "i......". As we can see in fig. 4.3-1, the waiting period of the CPU is collapsed into the execution time of the previous instruction, for example, $C_4$. 

Figure 4.3-1: The mapping between the concurrent top-level and the CPU, FPC top-level

```
(CPU_Top_Level $\land$ FPC_Top_Level) $\implies$ Concurrent_Top_Level
```
5.0 CONCLUSION

This report describes work on the verification of a floating-point coprocessor from three communicating implementing processes. Traditionally, hierarchical decomposition only involves vertical abstraction: an abstraction level is implemented by a single implementing level under it. In this project, three interacting processes are used to prove the correctness of the implemented process, that is, the FPC top-level interpreter.

Furthermore, we described the methodology for the composition of the CPU and coprocessor top-level specifications to form a more abstract view of the whole system consisting of the CPU and the FPC. Two levels of abstraction are used, the concurrent top level and the sequential top level. We believe this kind of abstraction approach presents a very interesting problem. Extending this approach, a complete system composed of many devices can be shown to correctly implement an abstract system abstraction.

let rep_ty = abstract_type 'interface' 'fetch';

state on the top level for APU:
    (f_ac, f_reg, c_ac, c_reg, mem)
env on APU top level:
    (ir)

note: (c_ac, c_reg, mem, ir) are actually belong to CPU state. But since FSTR instruction changes CPU state, c_ac, c_reg and mem has to be included here.

Arithmetic Instruction
    perform arithmetic operation on single or double precision floating point (real) numbers:
FADD, FSUB, FMUL, FDIV, FREM

These operations are entirely internal to the coprocessor.

\[(f_{ac}) + (f_{reg} 1) \rightarrow f_{ac}\]

----------------------------------------------------

let FADD = new_definition
('FADD',
"| (rep : 'rep_ty) (f_ac : fp) (f_reg : num->fp) (c_ac : num)

File: fstr_correct.ml
Author: Jing Fan
Date: Feb. 1991
Purpose: Verification of FPC top level against top level spec of the BIU, APU, and CPU service, in the case of an FSTR instruction.

Theories Used: aux, biu_top, biu_lemma, apu_top, apu_lemma,
cpu_service, service_lemma, fpc_top, induc, a.

This report presents work underway to formally specify and verify a floating-point coprocessor based on the MC68881. Our work uses the HOL verification system developed at Cambridge University. The coprocessor consists of two independent units: the bus interface unit to communicate with the cpu and the arithmetic processing unit to perform the actual calculation. Reasoning about the interaction and synchronization among processes using higher order logic is demonstrated.
