Results of crystallization studies on glasses with 20-40 mol% Y$_2$O$_3$ in the Y$_2$O$_3$-SiO$_2$ system are presented. Glasses were melted in W crucibles at 1900°C-2100°C in 1 and 50 atm N$_2$. Phase identification by X-ray diffraction and TEM indicated crystallization of the $\delta$, $\gamma$, $\gamma'$ and $\beta$-Y$_2$Si$_2$O$_5$, depending on melting and quenching conditions. Characterization of glasses was by differential thermal analysis (DTA), thermal gravimetric analysis (TGA) and chemical analysis including energy dispersive spectroscopy in the TEM. Heat treatment in an air atmosphere from 1100°C-1600°C increased the amount of crystallization and resulted in formation of Y$_2$SiO$_5$, cristobalite and polymorphs of Y$_2$Si$_2$O$_5$. The effect of 5 and 10 wt% ZrO$_2$ additions on crystallization was also studied.

Introduction

The use of high-temperature materials in applications such as gas turbine engines requires that the material not only be able to withstand the high temperatures, but also maintain acceptable mechanical properties during use at these temperatures, but also maintain acceptable mechanical properties during use at these temperatures or in cycling to these temperatures. Silicon nitride continues to receive extensive study as one possible material. We report here results on the crystallization of bulk glasses similar in composition to those found in the intergranular glassy grain boundary phases of sintered silicon nitride with yttria as the sintering aid. The silicon nitride composition studied contained a 6% by weight addition of Y$_2$O$_3$ to the starting silicon nitride powder as processed by NASA Lewis. This composition lies in the Si$_3$N$_4$-Y$_2$Si$_2$O$_5$-Si$_3$N$_4$O triangle of the phase diagram in Fig. 1. Since this powder contains silica present as a thin layer on each Si$_3$N$_4$ grain plus that resulting from addition to the starting powders or from possible oxidation during grinding, the exact composition of the intergranular glassy phase is difficult to determine.

Improvement in the high-temperature mechanical properties may result upon crystallization of a higher-melting-point crystalline phase from the glassy grain boundary phase. Crystallization of the glassy phase may be facilitated by the addition of a nucleating agent or by the alteration of the composition.

Review of Y$_2$O$_3$-SiO$_2$ Crystalline Phases

The diffraction data on Y$_2$Si$_2$O$_5$ crystalline polymorphs have been summarized by Liddel and Thompson. A review of the available data and some
of their own indicated that there are four polymorphs: α, β, γ, and δ. The low temperature polymorph, α, transforms to β as the temperature is increased. Figure 2 gives the temperature of the transformations and the densities of the various polymorphs of Y₂Si₂O₇. The structure of all polymorphs consists of Si₆O₁₄⁻⁴⁻ units. The X-ray powder diffraction file indicates that there are two different patterns of the γ phase, which are designated γ (JCPDS: 20-1416) and γ' (32-1448) in this paper. There are several polymorphs of the Y₂Si₂O₇ phase as discussed by Liddel and Thompson. The existence of the 2Y₂O₃·3SiO₂ phase as shown in the published phase diagram has not been confirmed, and, in fact, the existence of such a phase has been questioned. The volume change associated with the polymorphic inversions of Y₂Si₂O₇ is as large as 6.7% and may be significant in the crystallization of intergranular glassy grain boundary phases in silicon nitride (see these proceedings). The density of these glasses has not been reported.

**Experimental Procedure**

Reagent grade silica and yttrium oxide were ball milled for four hours with HSPN grinding media in dry alcohol and dried. The powder was dry milled for two hours then pressed into pellets and placed in tungsten crucibles for melting in a high-pressure nitrogen furnace. Powders were melted from 1900 °C to 2100 °C, depending on the composition, and were held for four hours under 50 atm nitrogen. Additional melts were also made in 1 atm nitrogen. No difference in properties or crystallization behavior was observed between these two melting conditions. In some cases repeated melts were made in the same crucible by the addition of more pellets. In general, this procedure of repeated melts in the same crucible is not recommended because the crucible sometimes cracked and physical and chemical alteration of the melt was observed, perhaps because of the initiation of reactions which resulted in the deposition of tungsten or volatilization of silica from the melt. It was necessary to break the crucibles to remove the melt. The as-melted samples were X-rayed to identify crystalline phases formed on cooling. Additional heat treatments on as-melted material were carried out in air from 1100 °C to 1600 °C and followed by phase identification using X-ray diffraction and TEM (transmission electron microscopy).

The compositions melted ranged from 20-40 mol% Y₂O₃. This compositional range is centered around the lower temperature eutectic region shown in Fig. 3, which is a modified version of the Y₂O₃-SiO₂ phase diagram without inclusion of the Y₂S₃ phase. This range covers compositions observed in the intergranular glassy grain boundary phase in as-processed NASA Lewis silicon nitride, assuming the absence of nitrogen within the glass. The exact chemical analysis of this phase is difficult to determine because the EDS (energy dispersive spectroscopy) system on the TEM at NASA Lewis has a Be window, which precludes soft X-rays such as those that arise from O or N. In earlier studies on these materials, no crystallization of nitried crystalline phases was observed. This may have been due to incomplete crystallization for the given heat treatment of the material or to the inherent difficulties of crystallizing small amounts of glassy material.

The primary glass composition studied was designated GSI. This is the eutectic composition between SiO₂ and Y₂Si₂O₇ and is similar to the intergranular glassy grain boundary composition without nitrogen in the as-processed 6Y silicon nitride. The formulation and as-melted composition is
given in Table I. The presence of tungsten will be discussed in the results section. Less than 0.2% nitrogen was found, indicating that little nitrogen was dissolved in the melt as a result of the 50 atm nitrogen overpressure. In addition, a GSII composition was melted containing 52 wt% Y₂O₃ and 48% SiO₂ and a Y₂Si₅O₁₀ composition. The GSZ5 and GSZ10 compositions are the same as GSI with 5 and 10 wt% ZrO₂ added as a nucleating agent. A 2Y₂O₃·3SiO₂, (Y₂S₃), composition was also melted to determine the stability of this crystalline phase.

Results

In all cases X-ray diffraction of the as-quenched melt indicated partially crystallization. The diffraction pattern from the as-melted GSI is shown in Fig. 4. The melt is amorphous but with a considerable amount of δ-Y₂Si₅O₁₀ phase present. Even in the case of sol-gel derived glasses at lower temperatures, partial crystallization was observed. Most of the melts contained the 6 phase, which would be expected from a rapid quench of the melts. However, in some cases the γ and β phases were observed. A satisfactory explanation cannot be given. The quench obtained in these melts was not a rapid one—estimated to be 270 °C/min. The furnace did not permit the more rapid quench that might have been obtained, for example, by pouring into a liquid. Exactly what melting and quenching conditions would result in the formation of the lower temperature polymorphs is not known. In some cases reheating of the melt might contribute to the existence of lower temperature polymorphs at higher temperatures, or the presence of tungsten in the melts may serve as a nucleating agent.

The GSII composition was phase separated on melting, which is expected from the phase diagram. The only exception to the partial crystallinity of the as-melted material was the Y₂S₃ composition which X-rayed amorphous (Fig. 5). Further experiments are being carried out to confirm this result. The GSZ5 and GSZ10 compositions consisted of β- and γ-Y₂Si₅O₁₀ respectively together with cubic ZrO₂.

The as-melted GSI composition produced β-, γ-, and δ-Y₂Si₅O₁₀ for different melts. Results of heat treatment of these melts are shown in Fig. 6. The X-ray diffraction pattern for a heat treatment of 24 h at 1300 °C is given in Fig. 7. In this case it would appear that all of the δ phase did not transform. In Fig. 8, a TEM micrograph of the GSI composition heat treated for 4 h at 1600 °C shows the presence of SiO₂ glass and δ-Y₂Si₅O₁₀, as expected from the phase diagram. The temperature range of these heat treatments was 1100 °C-1600 °C, and times ranged from the initial melt to 43 h. In general, the expected phases were formed, but in some cases metastable phases existed for long periods of time at a given temperature. Cristobalite was not present in sufficient amounts to be observed by X-ray diffraction but was identified by TEM. There was some evidence that the initial crystalline phases formed from the as-quenched melt may have determined the subsequent crystal phases formed. Further work needs to be done to clarify these results.

The results of heat treatment of the GSZ compositions containing 5 and 10 wt% ZrO₂ are shown in Fig. 9. For the GSZ5 composition β-Y₂Si₅O₁₀ was always observed with the cubic ZrO₂. In GSZ10 various phases crystallized including the γ and δ phases. The YS2 and YS3 results are shown in Fig. 10. Crystallization of Y₂Si₅O₁₀ and δ-Y₂Si₅Y at 1600 °C are the phases expected from the phase diagram with no formation of crystalline 2Y₂O₃·3SiO₂ as shown.
in the diffraction pattern in Fig. 11. Crystallization of a polymorph at temperatures above its conversion temperature is unexplained. It may have been due to formation of crystal nuclei on cooling from the melt and subsequent growth during heat treatment. Further crystallization studies are underway to better define the range of temperature stability of these polymorphs.

One of the more troublesome aspects of this investigation was the presence of tungsten in the melts. Obtaining a satisfactory crucible material was difficult. Materials tried included Pt, Rh, Ir and various alloys of these elements, BN, SiC, and Si₃N₄. None of these materials resulted in melts without dissolution and chemical alteration of the melt or the crucible material. Chemical analysis indicated that tungsten concentrations in the range 0.10-0.80 wt.% were dissolved or precipitated in the melts. In some cases, tungsten was deposited on the sides of the crucible or on the melt surface. It is not clear how this formed, but a possible mechanism is oxidation of tungsten to form a vapor which then deposited and decomposed to tungsten. Since little oxidation of tungsten used as shields in the furnace was observed, the concentration of oxygen in the furnace must have been very low. At these temperatures the vapor pressure of tungsten is too low to account for vapor transport of the tungsten metal. It is also possible that tungsten may have dissolved in the melts when liquid.

The TGA scan shown in Fig. 12 for a GSZ5 composition to 1800 °C indicates a 40% weight loss, most likely due to the volatilization of SiO. Melting was indicated at 1750 °C and a crystallization on cooling at 1450 °C. No crystallization or polymorphic inversions were observed on heating nor was there any indication of a glass transition. On cooling again, no polymorphic inversions were observed. Further studies are in progress to see if any crystallization can be detected by heat treatment during a DTA scan or in isothermal holds. DTA results on the GSZ compositions indicated possible crystallization on heating, but these results need to be examined further. It may be of interest to investigate other nucleating agents; however, most would lower the refractoriness of the glassy phase, which would be undesirable in the processing of silicon nitride.

Conclusions

Results of crystallization studies in the Y₂O₃-SiO₂ system have shown that, in general, the expected crystalline phases form when heat treated. It was also found that transformations were sluggish and in some cases phases could exist metastably. When the crystallization studies on the bulk glasses have been completed, the heat-treatment schedules which optimize crystallization will be applied to the 6Y silicon nitride composition to attempt to improve the high-temperature mechanical properties.

X-Ray diffraction and analytical electron microscopy have been used to study the
crystallization of the grain-boundary glass in a 6 wt% Y₂O₃-Si₃N₄ ceramic. Upon
crystallization, high densities of dislocations formed in the Si₃N₄ grains and remained
after 5 h at temperature. However, prolonged holds at the crystallization temperature
effectively annealed out the dislocations. Other features present in the microstructure are characterized.

Introduction

Microstructural characterizations of liquid-phase sintered Si₃N₄ have frequently been performed using scanning electron microscopy (SEM) to study fracture surfaces and identify failure sites.1-3 Lattice or structure imaging in the high resolution transmission electron microscope (TEM) has been carried out to detect small quantities of grain boundary glass.4-6 Other techniques such as energy dispersive spectroscopy (EDS) and energy loss spectroscopy (ELS) in the analytical electron microscope (AEM) have been used to quantitatively determine the chemical constituents of this glassy phase.7-9 Impurity phases in hot-pressed Si₃N₄ were carefully analyzed by Lou et al.9 Only recently, however, have microstructural studies been extended to examine the evolution of the microstructure with time and temperature upon crystallizing the glass. Bonnell et al.10-12 examined crystallization of cordierite (Mg₂Al₂Si₅O₁₄) and garnet (Y₃Al₅O₁₂) from MgO- and Y₂O₃-containing SiAlONs respectively. In the present work SEM, AEM, and optical microscopy have been utilized to examine the microstructures in NASA-6Y (6 wt% Y₂O₃) composition Si₃N₄ in the as-sintered condition and after a crystallizing heat treatment in N₂ at 1500°C for times from 5-20 h. We report here the results of AEM analysis.

Experimental

Materials and Sample Fabrication

Details of the starting powders and processing are given in a previous publication11 and are summarized in Table I. Two series of bars were examined: series A using GTE SN502 Si₃N₄ powder and series B using KBI-AME Si₃N₄ powder. Series A was sintered and crystallized in 25 atm N₂; series B was sintered and crystallized in 50 atm N₂.
Characterization

X-ray diffraction (XRD) of the as-treated surface of the 3 × 0.56 × 0.28 cm bars was carried out using a Philips APD 3600 powder diffractometer. AEM was performed on a Philips 400 EM with an Ortec 500 EDS system. The Be window on the EDS X-ray detector precludes detection of any element lighter than Na so that, unfortunately, neither N nor O could be analyzed with this system. Standard ceramographic grinding and polishing techniques were employed finishing with 3 μm diamond paste. Three-mm diameter TEM disks were ultrasonically cut from 1-mm thick slices of the bars, ground and polished to about 100 μm thickness, dimpled to 20 μm center thickness and ion milled to electron transparency using 5 kV Ar ions. Analysis of X-ray and electron diffraction patterns was facilitated by reference 12 for Si₃N₄ and 13 for Y₂Si₂O₅.

Results

X-ray Diffraction

Results of XRD analyses are given in Table II. Series A bars contain detectable amounts of Si₃ON₄ in all cases, even in the as-sintered material. This occurred even though series A had a lower starting SiO₂ content because of contamination during the long milling time (300 h), a higher SiO₂ content in the starting Si₃N₄ powder, and because of possible oxidation of Si₃N₄ upon milling. β-Si₃N₄ was the only other phase found in the as-sintered material but on crystallizing at 1500°C for 5-20 hours, β-Y₂Si₂O₅ peaks were also revealed.

As-sintered series B material was additionally subjected to a bend test in air at 1370°C before characterization which led to the formation of Y₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋₋/xhtml}

General Microstructure

The same general trends in the microstructural features observed in the TEM were seen for both series A and series B material. The main difference was that greater amounts of Si₃ON₄ were apparent in series A (detected by XRD) than in series B samples (not detected by XRD). However, Si₃ON₄ was frequently detected in the TEM when examining series B material even though the amount present must have been below the limits of detectability of the XRD unit (about 5 vol%).

As-sintered 6Y-Si₃N₄: Figure 1 is a bright-field TEM image of a typical area of the microstructure of 6Y material before crystallization consisting of hexagonal β-Si₃N₄ grains in a glassy matrix. The glass appears dark since it contains high atomic number Y which absorbs many of the electrons so that they do not contribute to the transmitted image. An EDS spectrum from the glass is also shown indicating the presence of Y and Si (O and N are not detected with this system). Low densities of dislocations were observed in about 40% of the Si₃N₄ grains examined (e.g. as arrowed in Figure 1). We intend to carry out EELS analysis of the as-sintered glass to determine the N content (if any) and O content.

*There are five polymorphs of Y₂Si₂O₅ as described in reference 22.
After 5 h at 1500°C: All specimens prepared for TEM after this heat treat-
ment were observed to crack on ion milling, a first indication that they were
under a large stress. β-Y2Si2O7 crystals were seen at the grain boundaries shown
as the dark phase in the bright field image of Fig. 2. The EDS spectrum for
this phase shows that the Y L,\textsubscript{1}, K\textsubscript{2} doublet peak is just smaller than the Si
K\textsubscript{1}, K\textsubscript{2} doublet peak. Note, however that spectra from this phase must be col-
lected from the edge of the sample away from Si\textsubscript{3}N\textsubscript{4} grains to stop X-rays
generated from the Si in the Si\textsubscript{3}N\textsubscript{4} from reaching the detector, otherwise
anomalously high Si peaks result. Figure 3 is a dark-field image where a single
reflection from the β-Y2Si2O7 has illuminated crystalline regions at the same
orientation extending over large areas of the microstructure. It appears that
most of the material that was glass before this heat treatment has crystallized
at this stage although high-resolution lattice imaging is needed to confirm this.

Figure 4 is a low magnification image of the microstructure. Note the
large number of strain fields in the Si\textsubscript{3}N\textsubscript{4} grains due to the presence of extensive
dislocation networks. Dislocations were observed in about 85% of the
grains examined and at much higher densities than in the as-sintered material.
Determining the presence of dislocations in a particular grain requires exten-
sive tilting to bring the grain to an orientation at which the dislocation is visi-
ble. Work is in progress to quantify the dislocation densities and to analyze
their habit planes and Burgers vectors. Figure 5 is a weak-beam dark-field im-
age of some of these dislocations using g = 0002. This technique is frequently
used when examining high densities of dislocations in ceramics since it images
only the core of the dislocation and removes the problem of overlapping strain
fields seen in conventional bright- or dark-field images.

After 10-20 h at 1500°C: Similar microstructures were observed in these
samples as after 5 h at 1500°C except that the dislocation densities were re-
duced almost to the level of the as-sintered material (Fig. 6). Specimens did
not crack on ion milling.

Other Observations
Several other features were observed in the microstructures using TEM
and are worthy of note.

α-Si\textsubscript{3}N\textsubscript{4}: Rounded grains of α-Si\textsubscript{3}N\textsubscript{4} were occasionally observed in all
specimens (e.g. arrowed in Fig. 6). Careful analysis of diffraction patterns
was required to distinguish these grains from the hexagonally-shaped β-Si\textsubscript{3}N\textsubscript{4}
grains. The α grains presumably are particles from the original starting powder
which did not dissolve during sintering. Observing large numbers of these grains
would indicate the need for longer sintering times or higher temperatures al-
though the amounts detected here were small and below the level of detect-
ability of the XRD unit for series B.

Precipitates in the β-Si\textsubscript{3}N\textsubscript{4}, Grains: Occasionally, small (about 150 nm
diameter) crystals were observed inside β-Si\textsubscript{3}N\textsubscript{4} grains. EDS analysis of the
crystal indicated the presence of silicon, and electron diffraction patterns iden-
tified them as being β-SiC, an impurity phase also observed by Lou et al. in
their TEM study of hot-pressing Si\textsubscript{3}N\textsubscript{4}. The crystals are faulted on (111)
giving rise to the streaks in the microdiffraction pattern of Fig. 7. The start-
ing powders used in the production of these samples are known to contain
about 0.1 wt% C\textsuperscript{11} which apparently forms into SiC during the solution-
precipitation sintering process. This observation has practical significance since it is known that carbon impurities reduce the oxidation resistance of Y\textsubscript{2}O\textsubscript{3}-Si\textsubscript{3}N\textsubscript{4} ceramics.\textsuperscript{14}

\textit{Si\textsubscript{3}ON\textsubscript{4} Crystals:} Detecting the presence of silicon oxynitride was relatively straightforward in the TEM due to the presence of stacking faults (and occasionally twins) on (100) planes as observed previously by Lewis et al.\textsuperscript{15} However, two distinct morphologies of Si\textsubscript{3}ON\textsubscript{4} were seen. Commonly, the Si\textsubscript{3}ON\textsubscript{4} crystals occurred as long, orthorhombic-shaped grains with the stacking faults running along the long (100) axis of the crystal (Fig. 8). The presence of streaks in the diffraction patterns was a strong indication that the grain was Si\textsubscript{3}ON\textsubscript{4}. Less common was the appearance of some Si\textsubscript{2}OH\textsubscript{2} crystallized with the same morphology as the Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} phase, i.e. crystallizing around the Si\textsubscript{3}N\textsubscript{4} grains (Fig. 9). This morphology was less inclined to contain stacking faults and so was more difficult to detect. EDS was required to distinguish this from Si\textsubscript{3}ON\textsubscript{4} from Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7}, as was careful analysis of diffraction patterns. In both morphologies, small crystals were seen inside the grains similar to the observation of Si\textsubscript{3}C crystals in Si\textsubscript{3}N\textsubscript{4} noted above. However, preliminary analysis suggests that these crystals are simply Si\textsubscript{3}ON\textsubscript{4} microcrystals at a different orientation to the parent grain and not a second phase.

Discussion
Crystallization of the grain-boundary glass to increase the refractoriness of Si\textsubscript{3}N\textsubscript{4} ceramics has been intensively studied since the work of Tsuge et al.\textsuperscript{16} in the Y\textsubscript{2}O\textsubscript{3}-Si\textsubscript{3}N\textsubscript{4} system. The NASA 6Y composition is chosen to lie in the oxidation-resistant Si\textsubscript{3}ON\textsubscript{4}-Si\textsubscript{3}N\textsubscript{4}-Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} triangle of the Si\textsubscript{3}N\textsubscript{4}-SiO\textsubscript{2}-Y\textsubscript{2}O\textsubscript{3} phase diagram and the microstructural results presented here confirm the presence of these phases along with the occasional impurity grains such as Si\textsubscript{3}C (Fig. 7). The increase in dislocation density in the Si\textsubscript{3}N\textsubscript{4} grains upon formation of Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} after 5 h at 1500°C was unexpected. Cracking of TEM specimens on ion milling is a clear indication that this material’s mechanical properties are adversely affected by this strain. The reduction in dislocation densities with prolonged heating at 1500°C, however, suggests that the dislocations can be annealed out without difficulty.

The reason for the appearance of dislocations is likely to be associated with a volume difference between the yttrium silicate glass and the first Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} crystals formed or volume differences between some of the Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} polymorphs. Alternatively, differences in thermal expansion between the various phases may lead to stress in the system. Densities of the polymorphic forms of Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} are available but the density of the glass is not. Experiments are currently being performed to determine the density of glasses with this composition. A volume change (increase or decrease) will impose a strain on the Si\textsubscript{3}N\textsubscript{4} grains, deforming them and causing dislocations to form. The dislocation microstructures formed in the crystallized material are typical of deformation-induced microstructures seen in other ceramics.\textsuperscript{17} According to Liddell and Thompson,\textsuperscript{18} \(\alpha\)-Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} transforms to the \(\beta\) form at 1225°C which should transform to \(\gamma\)-Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} at 1445°C. Since crystallization was carried out at 1500°C and \(\gamma\)-Y\textsubscript{2}Si\textsubscript{3}O\textsubscript{7} was never observed, the \(\gamma\) to \(\beta\) transformation must be rapid. Since the \(\beta\) to \(\alpha\) transformation did not occur when cooling below the \(\beta\) phase field it, however, must be sluggish. The volume change associated with the only polymorphic transformation to occur (\(\gamma\) to \(\beta\)) is small (0.2%) and so the most likely cause(s) of dislocation formation is (are) a volume change.
on crystallization from the glass or differences in thermal expansion behavior. However, as stated above, since the dislocations can be annealed out at the crystallization temperature, their formation need not affect the mechanical properties.

Hayashi et al. note a decrease in flexural strength after crystallization in pressureless-sintered Al2O3-Y2O3-Si3N4 ceramics which they attribute to a change in specific volume of grain boundary phases and difference of thermal expansion coefficients between Si3N4 and the crystallized phases.

While a thorough analysis of the dislocations observed in both as-sintered (presumably simple growth defects) and crystallized Si3N4 is not yet complete, a few words concerning previous studies of dislocations in this material seem in order. Studies of dislocations in Si3N4 are sparse. Evens and Sharp and Butler studied dislocations in hot-pressed and reaction-sintered materials. In both forms most of the dislocations had a <0001> Burgers vector, $b$, although other types of dislocation were present. Consideration of the strain energy associated with various types of dislocation in Si3N4 indicated that <0001> was the most stable Burgers vector whereas an analysis of dislocation mobility using the Peierls model suggested they would also be the most mobile with {1010} as the primary slip plane.

The observation that Y2Si2O5 crystallizes at a single orientation (i.e. as a single crystal) over large distances in the microstructure (Fig. 3) is interesting. Similar behavior was seen by Bonnell et al. in garnet (Y3Al2O12) crystallized in SiAlON grain boundaries but not when cordierite (Mg2Al4Si5O18) was crystallized. It is suspected that this behavior is a function of the ease or difficulty of nucleating the second phase; the easier nucleation is the less chance of crystals growing around the Si3N4 grains. Since crystallization of Y2Si2O5 is observed around several Si3N4 grains. Since crystallization of Y2Si2O5 is observed around several Si3N4 grains, it seems likely that complete crystallization of all the glass in that area had occurred even though the very thin intergranular regions were not illuminated in dark-field images. High-resolution TEM is planned to determine the extent of crystallization in this material. The crystallization morphologies of the Y2Si2O5 polymorphs formed from bulk glass are currently being studied in several complex systems.
