I am going to discuss a number of disposal options for space nuclear reactors and the associated risks, mostly in the long term, based on probabilities of Earth reentry.

The results are based on a five year study that was conducted between 1978 and 1983 on the space disposal of high level nuclear waste. It was a study actually begun at Lewis Research Center and later transferred to Marshall. The study provided assessment of disposal options, stability of disposal or storage orbits, and assessment of the long term risks of that bad stuff coming back to Earth.

Just recently, we completed an application study of nuclear thermal rockets to the lunar outpost scenario. I suppose most of the mission results that you have heard about have to do with Mars, but we have looked at it in terms of the moon and have examined, as part of that overall study, the case of the disposal options. Therefore, I will try to configure the presentations so that it will treat both the moon and Mars because many of the options are quite similar as I will show you.

Just to put it in perspective, for the lunar NTR study we looked at various combinations of NTR (see Figure 1) starting with one burn, that is just using it for the translunar injection (TLI) and then doing everything else chemical and aero. We end with a complete four burn, where the nuclear thermal rocket was the only propulsion system starting from LEO and going back into LEO.

The disposal options you have available that might work best depend very much on how the nuclear reactor is going to be used in the mission scenario. If it were only going to be used for TLI in this case, or transMars injection (TMI), then you would have a different kind of a disposal option, probably, than if it were going to be used and brought all the way back to Earth orbit, perhaps reused for several missions, but eventually disposed of in some way.

So what we mean by a spent reactor then is a device that has been operated and is radiologically active at end of life (see Figure 2). Normally the end of life would occur after normal operations and the number of reuses that it has been designed for. But, of course, end of life could also occur from a disabling accident, in which case a disposal option may be required too.

Then the question is what to do with that spent reactor to eliminate or minimize the subsequent hazard of the radioactive material coming back to Earth: being released in the biosphere.
I have listed some ten factors of consideration. If there is a need for disposal at the end-of-life, it's a fairly complex problem and needs to be considered in terms of trades (see Figure 2).

Let's look at some of the disposal options (see Figure 3 and 4).

They start with some moderate altitude Earth orbits that would be stable for some period of time, to a high earth orbit, which I called super GEO, somewhat above normal operations in GEO. If it were used for a lunar mission it could be a lunar surface delivery, including impact, which is probably not desirable, or an actual soft landing and storage on the moon.

The libration points of the Earth-moon and Earth-sun system are a possibility for disposal. If you are going to Mars you could leave it in Mars orbit. There are also libration points in the Mars system. Or we could put it into an Earth elliptical orbit, which does have a long-term risk of reentry, which I will describe. You could put it into a solar orbit that is stable for very long periods of time, which could apply either to the moon or Mars missions. Or, you could send it out of the solar system altogether, but the Delta V to escape the solar system is so high it would have a serious impact on mission performance.

To give a flavor of the kind of work that was done for the lunar application, we examined all of the cases shown in Figure 3 and 4. We looked at the situation of a disposal from a particular orbit state to another orbit state. We then calculated the disposal Delta V that would be required at the end-of-life. We found it varies quite a bit.

The lowest Delta V disposal was lunar gravity assist as applied to the NTR 1-burn case. You could deflect the trajectory to the trailing edge of the moon, take a lunar swing by and inject into a heliocentric orbit. A possible disposal solution for the NTR 4-burn case is a 1000 km circular orbit about Earth for a Delta V cost of about 300 meters per second.

The highlighted disposal options are the ones we actually examined in detail. We made comparisons against the nominal mission performance, and tried to determine what the disposal actually cost in terms of mass penalty.

In the case of the full NTR burn for lunar applications we examined two options. One was to put it into a heliocentric Earth-crossing orbit after coming back to LEO at end-of-life, or raise that orbit to a thousand kilometer altitude Earth orbit.

Now I am going to talk about reentry risk (see Figure 5). For example, a propulsion system failure might occur during injection prior to actually escaping the Earth. If we start in an orbit that has a high eccentricity with crossing of the lunar orbit distance, then
you would have a mean reentry lifetime of 200 to 700 years. Lunar collision would occur
with a much smaller lifetime, on the order of 50 years.

A VOICE: Are you talking about reentry into earth or an encounter with the moon?

MR. FRIEDLANDER: This combines both types of events. In other words, this was
not a disposal orbit but an orbit that resulted from some kind of a failure that had a
perigee close to Earth and crossed the lunar orbit. Subsequently, this "stay body" would
either reenter Earth's atmosphere, collide with the Moon, or be ejected from the Earth-
Moon system.

Now, what I want to talk about are some disposal options, including the stable solar
orbit, the heliocentric planet-crossing orbit, and then the moderate-altitude Earth orbit.

Figure 6 is a plot of heliocentric planetary distances. It shows the maximum and
minimum extent of Earth, Mars and Venus. It turns out there are two stable zones not
too far from Earth. One of them is between Earth and Mars, 1.17 to 1.19 AU circular
orbit. The other is between Earth and Venus. If you can get it into that circular orbit it's
going to stay there for a very long period of time - at least a million years.

To give you an example of what happens to that orbit, Figure 7 is a time history over a
million years of an orbit which was initially at 0.86 AU circular, between Earth and
Venus. It doesn't stay circular at all because of the mutual perturbation of the planets
and Earth. You can see the Venus aphelion and the Earth perihelion changing quite a
bit with time.

But, though it doesn't stay circular, the disposal orbit is stable to at least a million years
and probably much longer. That is to say, it does not become a planet-crossing orbit.

In fact, this was the nominal disposal destination selected for space nuclear waste after
consideration of all the possibilities.

Now let's look at a situation of an Earth-crossing orbit where the orbit starts out initially
with a perihelion of .85 AU and a aphelion at 1, so it left Earth on the way toward a
stable circular orbit. But let's suppose that the circularization burn at .85 failed and we
are left in an Earth-crossing orbit.

Figure 8 shows the results of the Monte Carlo statistical analysis. Initially the orbit only
crosses the Earth orbit, but because of the gravitational effects over the long term, it
actually begins to cross all the planets out to Jupiter and could be eliminated by collision
in various ways or by solar system ejection caused by Jupiter gravity perturbations.

In 54 percent of the cases it will eventually come back to Earth reentry. However, the
mean time for that to occur is 26 million years, which is a rather long time. There is
also a substantial probability of Venus collision, and once the object begins to cross Jupiter, at least ten percent of the time it will be ejected from the solar system altogether.

But the dominant event is an Earth collision and what is shown here is probability as a function of time for the various collision events.

So, for example, even though the mean lifetime greater than over 20 million years, at one million years the probability of Earth collision is 17 percent.

Figure 9 shows those results along with the sensitivity to orbit perihelion distance and inclination. For each of these cases the mean time to reentry is quite long, but there is a finite and not insignificant probability of Earth reentry occurring over shorter time periods.

A VOICE: Right now we are looking at an Earth reentry time of a "nuclear safe orbit" of 300 years. You are several orders of magnitude beyond that even in your worst case.

MR. FRIEDLANDER: That's quite true. This would be a very favorable result unless some particular design and analysis of the fission products showed that you really needed to provide nuclear safety for many, many thousands of years.

A VOICE: That's going to be a function of the safety groups to determine what is the minimum time we can have for reentry of any nuclear system in Earth orbit.

What I am trying to show is that, in the long term, we are talking about probabilities which might be quite acceptable. In fact, from my point of view, an Earth-crossing orbit is a fairly acceptable disposal place.

MR. FRIEDLANDER: You can get about a three and a half fold reduction in collision if you went ten degrees out of the elliptic plane. However, it's very costly to get ten degrees out of the elliptic plane.

If you are talking about disposal, you really want to put is someplace and be done with it. You don't want to be monitoring it for thousands of years.

A VOICE: I might want to reuse the materials.

MR. FRIEDLANDER: You might. In fact that was one of the considerations when it came to looking at space disposal of high level nuclear waste. Some people said they might want to use it in ten thousand years, so some people wanted to put it into Earth orbit. But that high level waste is bad stuff compared to a reactor.

Let's talk about the disposal in a moderate altitude Earth orbit. Consider a lunar or
Mars application that has been used for four burns and comes back to LEO. At that point, the easiest thing to do is add a very small Delta V is raise it up in altitude. Figure 10 shows the orbit lifetime against atmospheric drag and reentry.

If you place it at a thousand kilometers this would give you a lifetime against Earth reentry of 24 hundred years.

So if the safety time requirements are on the order of a few thousand years, you could put it into a moderate altitude circular orbit about Earth.

Figure 11 shows results from a recent paper by Chobotov and Wolfe in the Journal of Astronomical Sciences, January-March of this year. It's probably the latest update of a summary of the meteoroid and debris flux impact per year per square meter as a function of particle diameter.

This is the natural or man-made environment that an object put into a moderate altitude disposal orbit would face.

If you have a collision with a meteorite it's at about 20 kilometers per second impact speed. A collision with space debris tends to be around ten kilometer per second impact speed.

Even though the debris flux is low, it's getting worse and worse, and some people talk about trying to sweep some of that debris out. But, there is debris out there which could certainly do damage.

In future work, I would think that we might want to do a preliminary trade study of the disposal options for Mars applications to get a handle on what the impact on the nominal mission performance would be.

There are also short-time reentry risks. These would come about as a result of failure or accident environments. In this case, quantitative information about risk could not come out of the long-term statistical analysis that I have described. A different type of analysis would have to be performed.

Both short-term and long-term risks were examined in the previous studies of space disposal of nuclear waste. We looked at the reentry probability and the radioactive element inventory as a function of time. This was quite important for nuclear waste. I am not sure how important it is for the reactor operation but it is something that might need to be done. Eventually one would want to do an overall risk benefit assessment of disposal options.

Figure 10
In addition to the above sources of man-made debris, there have been numerous intentional breakups of spacecraft in orbit. Among these were a number of Soviet antisatellite tests at low altitudes, and United States windmill or spacecraft in orbits, such as the breakup of the Solar Wind satellite in 1983 and a Delta-180 stage in 1986.

On November 13, 1983, an Atlas rocket stage exploded into more than 400 trackable objects 1 cm in diameter and larger. This suggests the presence of several thousand or more small particles that cannot be tracked by ground-based radars. Recent orbital debris measurements are summarized in Fig. 3.114
