On the Measurement of Time for the Quantum Harmonic Oscillator

Scott R. Shepard

Cambridge, MA

Abstract

A generalization of previous treatments of quantum phase\(^1\) is presented. Restrictions on the class of realizable phase statistics are thereby removed, thus permitting “phase wavefunction collapse” (and other advantages). This is accomplished by exciting the auxiliary mode of the measurement apparatus in a time-reversed fashion. The mathematical properties of this auxiliary mode are studied in the hope that they will lead to an identification of a physical apparatus which can realize the quantum phase measurement.

1. The SG phase statistics

A satisfactory description of the phase of the quantum harmonic oscillator has recently been achieved by considering the realizable measurement\(^1\) of the non-Hermitian Susskind-Glogower (SG) phase operator\(^2\)

\[
ed^\phi \equiv \langle \hat{n} + 1 \rangle^{-1/2}\hat{a}.
\]  

Although it is not Hermitian, the SG operator does correspond to a realizable quantum measurement. It’s measurement statistics, however, can not be calculated from the familiar Hermitian operator rules (e.g. moments calculated via 

\[
\langle \psi | (e^{i\phi})^k | \psi \rangle, k = 1, 2, ... \text{ do not correspond to the SG operator’s realizable measurement statistics}.
\]

We have demonstrated a variety of ways in which the measurement statistics of the SG operator can be accessed \(^3\)-\(^5\). Perhaps the simplest of these is to form the phase wavefunction

\[
\psi(\phi) \equiv \langle \phi | \psi \rangle,
\]

from which the phase probability distribution, \(p(\phi) = |\psi(\phi)|^2/2\pi\), and it’s associated moments follow directly. This procedure is justified formally by the fact that the infinite energy eigenkets of the SG op-
(where \( k = 0, 1, 2 \ldots \)). These relations yield the correct form of the number/phase uncertainty principle[5]:

\[
(\Delta n^2)(\Delta \phi^2) \geq \frac{1}{4} (1 - 2\pi p(\pi))^2. \tag{10}
\]

Since we are dealing with a single harmonic oscillator (of frequency \( \omega \)), phase is related to time \( (\phi = \omega t) \) in a mod-2\( \pi \) sense, and number is directly related to energy \((\hat{n} = \hat{H}/\hbar \omega - 1/2)\). In this sense, the above constitutes a rigorous energy/time uncertainty principle for the quantum harmonic oscillator.

The class of realizable SG phase statistics, however, is restricted (by a Paley-Wiener theorem) due to the fact that \( \psi(\phi) \) is a one-sided Fourier series, i.e. this restriction stems from the absence of "negative number states" \( (\psi_n = 0 \; \forall n < 0) \). One aspect of this restriction is that \( \psi(\phi) \) is prohibited from identically vanishing over a non-zero interval — thus, delta-functions in phase are not allowed. In as much as we may desire a "wavefunction collapse" view of a phase measurement, the SG statistics appear to be incomplete. This dilemma, however, can be resolved by generalizing an alternate route (the product space formalism) to the SG statistics.

Fundamental to the realizable measurement of any non-Hermitian operator is the existence of an auxiliary noise source. Zero-point fluctuations from this auxiliary mode prevent a simultaneous, perfectly precise, measurement of the non-commuting real and imaginary parts of the non-Hermitian operator (so that the uncertainty principle is not violated). We can study the interaction of our original system of interest (Hilbert space \( \mathcal{H}_s \)) with this auxiliary system (Hilbert space \( \mathcal{H}_a \)) by working in the product space \( \mathcal{H} = \mathcal{H}_s \otimes \mathcal{H}_a \). The extension of the SG operator onto \( \mathcal{H} \) is [3]

\[
\hat{\varphi} = (e^{i\phi})_s \otimes \hat{v}_a + \hat{v}_a \otimes (e^{i\phi})_s, \tag{11}
\]

where \( \hat{v} \equiv |0\rangle \langle 0| \). This extension has eigenkets (of non-zero eigenvalue), \( \hat{\varphi} \phi' = e^{i\phi} \phi' \), given by

\[
|\phi'\rangle = |0\rangle_a \langle 0|_a + \sum_{n_s = 1}^{\infty} e^{-in_s\phi} |n_s\rangle \langle n_s|_a \tag{12}
\]

These reside on a subset, \( \mathcal{H}' \), of \( \mathcal{H} \) which is defined by the property \( n_s n_a = 0 \). When the auxiliary mode is in the vacuum state \( (n_a = 0) \), the \( \hat{\varphi} \) measurement yields the SG statistics and their attendant Paley-Wiener restriction.

2. Beyond the SG statistics

We can go beyond the SG statistics by exciting the auxiliary mode to create an arbitrary state on \( \mathcal{H}' \):

\[
|\psi\rangle' = \sum_{n_s = 0}^{\infty} \psi_{n_s, 0} |n_s\rangle \langle 0|_a \tag{14}
\]

\[
+ \sum_{n_a = 1}^{\infty} \psi_{0, n_a} |0\rangle \langle n_a|_a. \tag{15}
\]

For simplicity, let \( N \equiv n_s - n_a, \psi_N \equiv \psi_{N, 0} (\forall N > 0) \), and \( \psi_N \equiv \psi_{0, -N} (\forall N < 0) \). The generalized phase wavefunction,

\[
\psi'(\phi) \equiv \langle \phi|\psi\rangle' = \sum_{N = -\infty}^{\infty} \psi_N e^{-iN\phi}, \tag{16}
\]

is a two-sided Fourier series. The the Paley-Wiener restriction is removed and \( \psi'(\phi) \) can "collapse" to a delta-function. The fact that the class of \( \psi'(\phi) \) is more general than (and includes) the class of \( \psi(\phi) \) should prove useful for various optimizations. Indeed, Shapiro[4] has pointed out that error-free communication could in principle be achieved by exploiting the newly acquired generality described herein.

Provided that neither of our two modes is purely in the vacuum state, the excitation which creates a state on \( \mathcal{H}' \) is not arbitrary in that the \( n_s n_a = 0 \) property creates an entanglement. Thus, in general, the original system and auxiliary modes are not statistically independent on \( \mathcal{H}' \), i.e. \( |\psi\rangle' \neq |\psi\rangle_s |\psi\rangle_a \). Denoting the probability that a measurement of \( \hat{n}_a \) yields the outcome \( n \) by \( |\psi_n\rangle^2 \), we see that \( |\psi_n\rangle^2 = |\psi_{n, 0}\rangle^2 (\forall n \geq 1) \), whereas \( |\psi_0\rangle^2 = |\psi_{0, 0}\rangle^2 + \sum_{n = 1}^{\infty} |\psi_{0, n}\rangle^2 \) (similarly for
I(1\right). In spite of the lack of statistical independence, we can therefore assign any individual probability distributions for \( n \) and \( n_a \) that we wish, provided that

\[
|\psi_{0,0}|^2 = (|\psi_0^2| + |\psi_0^2| - 1) \geq 0
\]  

(17)
is satisfied.

The auxiliary mode can be interpreted as a time-reversed mode in the following sense. Consider the case of the auxiliary mode being in the vacuum state \( (n_a = 0) \). Denote the initial state by \( |\psi_0\rangle \). The state (in the Schrödinger picture) after time evolution of an amount \( \tau \) is

\[
|\psi_{\tau}\rangle' = e^{-i\hbar \omega \tau} |\psi_0\rangle',
\]
so that the relation of the phase representations of the initial and delayed states is simply

\[
\psi_{\phi}(\phi) = \psi_{0}'(\phi + \omega \tau) \quad (n_a = 0).
\]

(19)

Now consider the case of the original system being in the vacuum state \( (n_a = 0) \). The Schrödinger picture of the delayed version of an initial state \( |\psi_0\rangle \) is

\[
|\psi_{\tau}\rangle' = e^{-i\hbar \omega \tau} |\psi_0\rangle'.
\]

(20)
The initial and delayed phase representations for this case are related by

\[
\psi_{\phi}'(\phi) = \psi_{0}'(\phi - \omega \tau) \quad (n_a = 0).
\]

(21)

Thus the two modes are time-reversed in that, under time evolution, the \( n_a \geq 1 \) portion of the generalized phase wavefunction "moves backwards" with respect to the \( n_a \geq 1 \) portion.

Consistent with the time-reversal property, the auxiliary mode serves the topological role of a "negative energy" mode in Hilbert space. The SG operator is a pure lowering operator which stops at the vacuum:

\[
e^{-\phi} |n\rangle = |n - 1\rangle \quad (n \geq 1)
\]

(22)

\[
e^{-\phi} |0\rangle = 0.
\]

(23)

It cannot lower below the vacuum since we have not allowed negative number (negative energy) states for the quantum harmonic oscillator. Its extension, \( \hat{\Psi} \), however, lowers the original system mode number

\[
\hat{\Psi} |n_a\rangle |0\rangle_a = |n_a - 1\rangle_s |0\rangle_a \quad (n_a \geq 1),
\]

(24)

then continues through the vacuum

\[
\hat{\Psi} |0\rangle_s |0\rangle_a = |0\rangle_s |1\rangle_a,
\]

(25)

and raises the auxiliary mode number

\[
\hat{\Psi} |0\rangle_s |n_a\rangle_a = |0\rangle_s |n_a + 1\rangle_a.
\]

(26)

Topologically, it is as if \( \hat{\Psi} \) continues to lower below the vacuum into the auxiliary ("negative energy") mode. The visualization of this behavioral aspect can be facilitated by simply relabeling the \( \hat{\mathcal{H}} \) number states according to the value of \( N = n_a - n_a \).

The auxiliary mode has to be an irreparable part of the physical apparatus which realizes the quantum phase measurement (so that the uncertainty principle is satisfied and so that the phase wavefunction can collapse). All of the aforementioned mathematical properties must be physically realized in the measurement apparatus. These restrictions should prove useful in determining an apparatus which will realize the quantum phase measurement.
