ABSTRACT

Several numerical simulations of the transient flow of helium in an expansion tube are presented in an effort to identify some of the basic mechanisms which cause the noisy test flows seen in experiments. The calculations were performed with an axisymmetric Navier-Stokes code based on a finite-volume formulation and upwinding techniques. Although laminar flow and ideal bursting of the diaphragms was assumed, the simulations showed some of the important features seen in the experiments. In particular, the discontinuity in tube diameter at the primary diaphragm station introduced a transverse perturbation to the expanding driver gas and this perturbation was seen to propagate into the test gas under some flow conditions. The disturbances seen in the test flow can be characterized as either small-amplitude, low-frequency noise possibly introduced during shock compression or large-amplitude, high-frequency noise associated with the passage of the reflected head of the unsteady expansion.

\( \mu \) : coefficient of viscosity, Pa.s \\
\( \nu \) : frequency, s\(^{-1}\) \\
\( \Omega \) : cell volume, m\(^3\) \\
\( \Omega' \) : volume per radian for the axisymmetric cell \\

\(< \bullet >\) : cell-averaged value
Subscripts

0 : conditions immediately behind the shock
1 ... 20 : gas state as shown on Fig. 1
\( e \) : conditions just outside the boundary layer
\( i \) : interaction of expansion with driver-gas/test-gas interface
\( v \) : viscous contribution
\( w, \text{wall} \) : wall value
\( x, y \) : cartesian components
1 Introduction

The expansion tube is a member of the family of pulse-type aerodynamic facilities designed to provide high enthalpy test gas for short durations. It has a fundamental advantage over the reflected-shock tunnel because its operating cycle does not involve the stagnation of the heated test gas. Hence, it can provide a final test flow with low ionization and low dissociation. Initial theoretical studies of the expansion tube [1] indicated that such a machine could provide a wide range of test flows by simply altering the initial filling pressures. However, operational experience (see e.g. [2, 3]) indicated that the test flow was often contaminated by large-amplitude disturbances. Here, some numerical simulations of an entire (but idealized) expansion tube are presented in order to provide some insight into the mechanisms causing the disturbances in the test flow. The specific facility configuration and the flow conditions considered here are based on the experimental perfect-gas study undertaken by Shinn and Miller [3].

1.1 Facility Operation

An expansion tube is essentially a single tube divided into three sections by “primary” and “secondary” diaphragms as shown in lower part of Fig. 1 (which is reproduced from [3]). The strong primary diaphragm separates the driver tube and the intermediate (or shock) tube while the light secondary diaphragm separates the intermediate tube from the acceleration tube. The intermediate and acceleration tubes have the same diameter. Initially, the driver tube contains a “driver gas” at high pressure (state 4) while the intermediate tube contains the test gas (state 1) and the acceleration tube contains a low pressure “acceleration gas” (state 10). The aerodynamic model to be tested is located near the downstream end of the acceleration tube.

The operation of the facility, starting with the rupture of the primary diaphragm at \( t = 0 \), is shown schematically in the top part of Fig. 1. The numbering of the flow states is the same
as that introduced by Trimpi [1]. High pressure driver gas expands into the intermediate tube (state 3) and shock-compresses the test gas (state 2). Simultaneously an expansion fan travels upstream into the driver tube. On reaching the end of the intermediate tube, the shock ruptures the secondary diaphragm (ideally without producing disturbances) and the leading portion of the shock-compressed test gas is allowed to expand into the acceleration tube to reach the test flow conditions (state 20). The expanded test gas will have a high velocity (typically 6 – 8 km/s) and a relatively low temperature (several hundred degrees Kelvin).

As shown in Fig. 2, test time commences after the passage of the test-gas/acceleration-gas interface and ideally finishes with the arrival of the downstream end of the unsteady expansion (and a corresponding increase in Pitot pressure). Not all of the shock-compressed test gas is expanded to the test flow state (20) and so test times are short, typically measured in tens to hundreds of microseconds. Unfortunately, ideal operation of the facility is seldom realized as test flows are typically very noisy and may have peak-to-peak variations of 50% in Pitot pressure. Note that, depending on the length of the tube sections and the initial gas states, the arrival times for the various waves at the test-section may change. Of particular importance is the reflected-head of the unsteady expansion (of the test gas). This wave is generated when the upstream-head of the unsteady expansion reaches the driver-gas/test-gas interface. A partial reflection will occur and, for some test conditions, this wave (which travels along a $u + a$ characteristic) will arrive at the end of the acceleration tube before the unsteady expansion itself.

1.2 Previous Studies

The cause of the test flow disturbances has been the focus of several studies. Shinn and Miller [3] made experimental measurements in the NASA Langley facility using helium as the test gas, driver gas and acceleration gas in order to eliminate chemical effects. They observed that most of the operating conditions resulted in test flows which were very noisy but identified
an optimum condition \((P_1 = 3.45 \text{ kPa}, \ P_{10} = 16 \text{ Pa})\) with approximately 300 \(\mu s\) test time (with only moderately small disturbances) before the onset of large-amplitude fluctuations in the Pitot pressure. A large dip in the Pitot pressures was observed for values of \(P_{10}\) significantly larger than 20 \(\text{ Pa}\) and this was attributed to boundary layer transition. They also identified the importance of the diaphragm dynamics on the quality of the test flow, especially at low initial pressures. However, they did not identify the mechanism causing the early disturbances in the test gas.

More recently, equivalent experiments [4] using both helium and argon as the working gas were performed at the University of Queensland to check the Langley results [3] and see if the useful range of test conditions could be expanded. In conjunction with these experiments, a numerical study (based on quasi-one-dimensional modelling) was undertaken [5] to see if the test gas disturbances could be caused by “blobs” of driver gas being accelerated through the expanding test gas. It was concluded that, even if the blobs existed, they would not arrive early enough to cause the test-flow disturbances. However, the reflection of the unsteady expansion off the driver-gas/test-gas interface could (under some conditions) arrive early enough to introduce the noise. Test time estimates based on this mechanism are given in [6] and are consistent with the present numerical simulations.

Paull [4, 7, 8] has pursued the possibility of acoustic disturbances being generated near the primary diaphragm station and then being propagated through the unsteady expansion of the driver gas. A family of transverse waves can exist and, when propagated through the expansion, will undergo a frequency shift such that a single dominant frequency will emerge. Transmission of these waves across the interface and into the test gas is assumed to be determined by the acoustic impedance mismatch at the interface. For situations where the sound speed in the test gas is much larger than that in the expanded driver gas, attenuation of the waves in the test gas should occur. Otherwise, a significant fraction of the noise will be transmitted. This acoustic model is seen to be a reasonable approximation to the simulations presented here.
2 The Numerical Method

The computations reported here were performed with a finite-volume upwind code based on the full Navier-Stokes equations. The code is described briefly here but further detail is available in [9].

2.1 Governing Equations

For an axisymmetric flow (with \( y \) as the radial coordinate), the finite-volume formulation of the Navier-Stokes equations may be expressed as

\[
\frac{d < U >}{dt} + \frac{1}{\Omega'} \int_S (y \mathbf{F} - y \mathbf{F}_v) \, dy - \frac{1}{\Omega'} \int_S (y \mathbf{G} - y \mathbf{G}_v) \, dx = \mathbf{Q}'
\]

where \( < \cdot > \) indicates a volume average, \( \Omega' \) is the volume per radian and \( S \) is a contour in the \((x, y)\)-plane around the volume. The \( U, F \) and \( G \) vectors are

\[
U = \begin{bmatrix} \rho \\ \rho u \\ \rho v \\ \rho E \end{bmatrix}, \quad yF = y \begin{bmatrix} \rho u \\ \rho u^2 + P \\ \rho uv \\ \rho Eu + Pu \end{bmatrix}, \quad yG = y \begin{bmatrix} \rho v \\ \rho uv \\ \rho v^2 + P \\ \rho Ev + Pv \end{bmatrix}.
\]

Except for the "\( y \)" premultiplying factor, these terms are the same as those in the planar two-dimensional situation. The viscous terms are

\[
y \mathbf{F}_v = \begin{bmatrix} 0 \\ y \tau_{xx} \\ y \tau_{xy} \\ y \tau_{xx}u + y \tau_{xy}v + y q_z \end{bmatrix}, \quad y \mathbf{G}_v = \begin{bmatrix} 0 \\ y \tau_{yx} \\ y \tau_{yy} \\ y \tau_{yx}u + y \tau_{yy}v + y q_y \end{bmatrix},
\]

where

\[
\tau_{xx} = 2\mu \frac{\partial u}{\partial x} + \lambda \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{v}{y} \right),
\]

\[
\tau_{yy} = 2\mu \frac{\partial v}{\partial y} + \lambda \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{v}{y} \right),
\]

\[
\tau_{xy} = \tau_{yx} = \mu \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right),
\]

and

\[
q_x = -k \frac{\partial T}{\partial x}, \quad q_y = -k \frac{\partial T}{\partial y}.
\]
Treating the viscous contributions in the form $y\tau$ avoids any difficulties with the geometry singularity at $y = 0$. The effective source term is

$$Q' = \begin{bmatrix} 0 \\ (P - \tau_{yy})A/\Omega' \end{bmatrix}, \quad \text{where} \quad \tau_{yy} = 2\mu \frac{v}{y} + \lambda \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{v}{y} \right).$$  \quad (8)

To augment these equations, the equation of state for a calorically perfect gas is used

$$P = \rho(\gamma - 1)e,$$  \quad (9)

with $\gamma = 1.667$ and $R = 2077 \, J/kg/K$ for helium. The corresponding specific heats are $C_v = 3114 \, J/kg/K$ and $C_p = 5191 \, J/kg/K$. The first coefficient of viscosity is evaluated as

$$\mu = 5.023 \times 10^{-7} \, T^{0.647} \, Pa.s,$$  \quad (10)

and the second coefficient is obtained from Stokes’ hypothesis $\lambda = -\frac{2}{3}\mu$. Also, a constant Prandtl number of 0.67 is assumed.

### 2.2 Numerical Implementation

The flow domain in the $(x,y)$-plane is discretized as a structured mesh of quadrilateral cells with flow properties stored at the cell centres. At each time step, the inviscid-flux vectors (2) are evaluated by first applying a generalized MUSCL interpolation scheme [10] to obtain “left” and “right” states at the midpoints of the cell interfaces. A locally one-dimensional (approximate) Riemann solver is then applied to obtain the interface flow properties during the time step. The spatial derivatives used in the viscous flux vectors (3)-(7) are obtained at the cell vertices by applying the divergence theorem. The source term (8) is evaluated at the cell centres. The line integrals in (1) are then evaluated using the midpoint rule and the solution advanced in time.

Although a predictor-corrector time-stepping scheme was available in the code, the solutions shown in the following sections have used Euler time stepping in order to reduce the
required cpu time for each simulation. Several simulations of the initial shock compression of
the test gas were run to investigate the effect of grid resolution and choice of time-stepping
scheme [11]. Except for the fine-scale features, there were few differences in the solutions for
both Euler time-stepping and predictor-corrector time-stepping on a (coarse) 1604 × 20 grid.
The differences between these coarse-grid solutions and the solution on the (fine) 2406 × 30
grid were also small. The limit on the number of cells was set by the memory available on
the local workstations (64 Mbytes) and the desire to fit the jobs within the 8 Mword queues
on a Cray-YMP located at the NASA Langley Research Centre, USA.
3 Simulation Results

Figure 3 shows the flow domain considered in the simulations. The flow is considered to be axially symmetric with the flow domain extending radially from the axis to the tube wall and axially from the closed end of the driver tube to the end of the acceleration tube where it enters the test section of the facility. Dimensions are shown in the figure. Using the program in [11], the grid was generated in three pieces, one for each section of the facility. The number of cells and the clustering toward the tube wall remained constant along the length of the domain and the cell size remained constant in the axial direction. The radial distance from the outermost cell-centres to the intermediate- and acceleration-tube walls is $3.87 \times 10^{-4}$ m. Although the use of an axisymmetric geometry minimizes the computational resources required for the simulation, it also precludes genuinely three-dimensional disturbances which may constitute a significant portion of the experimentally observed noise.

While the change in tube radius at the primary-diaphragm station is included, neither the diaphragm nor the square transition section downstream of this point is modelled. Instead, the simulations start with high-pressure reservoir conditions upstream of the primary diaphragm station and intermediate-tube initial conditions downstream of the same station (and into the acceleration tube). The simulations are allowed to proceed until the primary shock reaches the secondary-diaphragm station and, at that point in time, the conditions downstream of the secondary diaphragm are reset to the acceleration-tube initial conditions. Thus, the bursting of the diaphragms is considered to be ideal in the following calculations. This is in contrast to the experimental observation that the flow quality is very sensitive to rupture behaviour of the diaphragms [2, 3] but, as will be seen in the results, the key features governing the quality of the test flow are captured.
3.1 Initial State

All of the simulations used the nominal driver tube conditions given in [3]. These are

\[ P_4 = 33 \text{ MPa}, \quad u_4 = 0, \quad T_4 = 330 \text{ K}, \quad \rho_4 = 48.15 \text{ kg/m}^3, \quad e_4 = 1.028 \text{ MJ/kg}. \]

As discussed in [3] the nominal driver-tube temperature may be lower than the actual gas temperature at primary-diaphragm rupture where a maximum value of \( T_4 = 390 \text{ K} \) was estimated. The test gas and acceleration initial conditions are

\[ T_{10} = T_1 = 300 \text{ K}, \quad e_{10} = e_1 = 0.934 \text{ MJ/kg}, \quad u_{10} = u_1 = 0, \]

with pressures and densities as specified in Table 1.

For cases 1a and 1b, the conditions were chosen to approximate the optimum conditions identified in the experiment [3] and two different grids were used to check for sensitivity to grid resolution. Cases either side of this optimum condition were then considered. Case 2 has a higher intermediate-tube pressure where large-amplitude noise was observed at an earlier time in the experiment. Case 3, with a low intermediate-tube pressure, also was observed to have a noisy test flow early in the test time. Finally, case 4 considers the condition with high acceleration-tube pressure where (for the Langley expansion tube) a large dip in Pitot pressure was observed shortly after the arrival of test flow [3].

3.2 Case 1: \( P_1 = 3.45 \text{ kPa}, \quad P_{10} = 16 \text{ Pa} \)

This condition was chosen to be the starting point for the study because it was identified as the best operating condition in the experiment [3]. The observed test time was approximately 300 \( \mu \text{s} \) before large-amplitude noise contaminated the test flow. During the test time, moderately small disturbances in Pitot pressure were observed. Two calculations were performed and details of the computational resources are shown in Table 2. The global time step was limited so that the maximum Courant-Friedrichs-Lewy (CFL) number in any cell
was approximately 0.5. This maximum value occurred in the flow region just behind the shock.

Case 1a used a “coarse” grid of 1604 cells axially by 20 cells radially while case 1b used a “fine” grid of 2406 x 30 cells. (Refer to [11] for the coarse grid results.) The computed results, including the timing of events such as the passage of the shock and contact surfaces, were largely the same. There were, however, some differences in the details of the contact surfaces and the noise introduced to the test flow. In particular, the coarse grid attenuated some of the noise and limited the highest frequency seen in the simulation.

Figure 4 summarizes the calculation for case 1b as a wave diagram. The data points plotted were obtained from the individual plots of the density field shown later. Note the small size of the slug of compressed acceleration gas (state 20). The position of the long dashed line, denoting the downstream-tail of the unsteady expansion of the test gas, was estimated by its arrival at \( z = 24 \text{ m} \) while the short-dashed line represents the propagation of the leading edge of the reflected expansion and the asterisk denotes the arrival of large-amplitude noise at the end of the acceleration tube \( (x \approx 24 \text{ m}) \). This reflected expansion is the result of the interaction between the upstream-head of the unsteady expansion and the test-gas/driver-gas interface. The test time (state 5) for this case starts after the passage of the test-gas/acceleration-gas interface and stops with the arrival of the downstream tail of unsteady expansion.

3.2.1 Shock Compression of the Test Gas

Density contours for the shock compression of the test gas are shown in Fig. 5. For each frame, 81 contours have been plotted over the range \(-6.0 \leq \log_{10} \rho \leq 2.0\). Although the shock has remained essentially planar, the driver-gas/test-gas interface has become quite distorted by \( t = 2.0 \text{ ms} \). Boundary layer effects are present (as can be seen by the contact surface being left behind along the tube wall) but they are not well resolved in this part of the calculation.
Of special interest is the train of transverse waves following the interface. These transverse waves show up clearly in the contours of the radial velocity as shown in Fig. 6 where it appears that the disturbances are introduced at the primary diaphragm station. Note that the axial scale is highly compressed and the actual Mach angles are much shallower than those that appear in the figure. Significant noise is present in the shocked test gas.

Figure 7 shows the axial variation of flow properties at $t = 1.0 \text{ ms}$ together with the estimated properties for a purely one-dimensional situation. Except for some noise, the levels are in general agreement. Although the axisymmetric simulation exhibits a higher shock speed than the one-dimensional case, tables 3 and 4 show that the computed shock speed is still lower than that measured in the experiment. The large experimental value was discussed in [3] and may be partly due to a low estimate for the initial driver-gas temperature. Also, note the variation in shock speed over this phase of the facility operation (see table 4).

### 3.2.2 Unsteady Expansion of the Test Gas

The unsteady expansion of the test gas is shown in Fig. 8. Viscous effects are more important in the acceleration tube and a very thick boundary layer is established behind the shock and test-gas/acceleration-gas interface. The separation distance of the shock and contact remains essentially constant from $t = 2.5 \text{ ms}$ to $t = 4.0 \text{ ms}$ because a balance has been reached between the mass flow of acceleration gas entering through the shock and the mass flow bleeding into the boundary layer [12]. The hot acceleration gas passing into the boundary layer tends to accumulate just upstream of the test-gas/acceleration-gas interface and form a large bulge in the boundary layer (at $x \simeq 23 \text{ m}, t = 4.5 \text{ ms}$). It is not until the last frame ($t = 5.0 \text{ ms}$) that any significant level of noise is evident in the expanding test gas.

Figure 9 shows the axial variation of flow properties at $t = 4.4 \text{ ms}$. There are very obvious disturbances in the region of the expanded driver gas (state 3) and, on close inspection of the pressure distribution, some small-amplitude disturbances can be seen near the downstream
end of the unsteady expansion of the test gas (at \( x \approx 22 \text{ m} \)). Paull's acoustic wave model [7] suggests that the broadband disturbances, introduced upstream of an unsteady expansion, will tend to focus to a single frequency near the downstream tail of the expansion. For the expanding driver gas, Paull estimates a "focus" frequency \( \nu_F = 11.9 \text{ kHz} \) while the perturbations seen in the present simulation have an approximate frequency \( \nu = 10.2 \text{ kHz} \). These figures are in reasonable agreement.

The very high temperature of the shocked acceleration gas enhances the diffusion near the test-gas/acceleration-gas interface. Figure 10 shows details of the shock and test-gas/acceleration-gas interface region. The bulge seen very clearly at \( x \approx 23 \text{ m}, \ t = 4.5 \text{ ms} \) in Fig. 8 is no longer as obvious in this "true-shape" plot. Plotting the velocity field in a frame of reference which is stationary with respect to the shock and contact surface clearly shows the bleeding of shocked acceleration gas out of region 20 and into the boundary layer. Estimates of the separation distance between the shock and contact surface (i.e. the length of region 20) can be made using the theory presented in [12]. Using the expression

\[
L_{20} = \frac{r_w^2}{4\beta^2} \left( \frac{\rho_{e,0}}{\rho_{w,0}} \right)^2 \frac{u_{e,0}}{u_w - u_{e,0}} \frac{u_{e,0} \rho_{w,0}}{\mu_{w,0}} \tag{11}
\]

together with the parameter estimates

\[
\beta = 2.12, \quad u_w = U_{s,10} = 5900 \text{ m/s}, \quad u_{e,0} = 1200 \text{ m/s},
\]

\[
\rho_{e,0} = 1.0 \times 10^{-4} \text{ kg/m}^3, \quad \rho_{w,0} = 2.484 \times 10^{-4} \text{ kg/m}^3, \quad \mu_{w,0} = 2.012 \times 10^{-5} \text{ Pa.s},
\]
a separation length of 0.20 m is obtained. This is in reasonable agreement with the 0.22 m length observed in Fig. 10 but it should be noted that the value of \( L_{20} \) obtained from eqn. (11) is very sensitive to the estimated parameters.

### 3.2.3 Histories of the Test Flow Properties

Histories of the centreline test-flow properties near the exit of the acceleration tube are shown in Fig. 11. Features that can be identified include the passage of the shock and
the test-gas/acceleration-gas interface at times \( t = 4.45 \text{ ms} \) and \( t = 4.48 \text{ ms} \) respectively. These events are followed by a gradual variation in properties possibly due to a constriction of the effective tube diameter associated with the passage of the bulge (identified in Fig. 8). The downstream tail of the unsteady expansion arrives at \( t = 4.63 \text{ ms} \) when average pressure and density begin to rise while Mach number and velocity decline. It is in the period \( 4.6 < t < 5.0 \) that a “small-amplitude” fluctuation is evident. The period of this perturbation is approximately \( 40 \mu\text{s} \), which corresponds closely to the period observed in the Shinn and Miller [3] experiment and the more recent calibration measurements [13].

The fluctuations increase in both the amplitude and the frequency with the arrival of the reflected head of the unsteady expansion at \( t = 5.04 \text{ ms} \). This wave originates with the rupture of the secondary diaphragm and travels along a \( u_2 - \alpha_2 \) characteristic until it strikes the driver-gas/test-gas interface. There is both transmission into the driver gas and partial reflection downstream along a \( u + \alpha \) characteristic thus admitting more disturbances into the expanding test gas. The arrival time for this wave (at the exit plane of the acceleration tube) may be estimated as described in [6]. The process starts at \( x' = 0, \ t' = 0 \) with the rupture of the secondary diaphragm. The upstream head of the unsteady expansion intersects the driver-gas/test-gas interface at \( t' = \Delta t_i, \ x' = (u_2 - \alpha_2) \Delta t_i \). Refer to tables 5 and 6 for particular values. The propagation time of the wave through the unsteady expansion may be obtained by integration along a \( u + \alpha \) characteristic for which the Riemann invariant is [14]

\[
\frac{u_s}{\gamma - 1} + \frac{2}{\gamma - 1} a_s = \bar{U} = u + \frac{2}{\gamma - 1} a .
\]  

(12)

Within the centred expansion we have

\[
\frac{x'}{\nu'} = u - \alpha ,
\]  

(13)

and this may be substituted into equation (12) to obtain

\[
a = \frac{\gamma - 1}{\gamma + 1} \left( \bar{U} - \frac{x'}{\nu'} \right) ,
\]
\[ u = \frac{\gamma - 1}{\gamma + 1} \left( U + \frac{2}{\gamma - 1} \frac{x'}{v} \right) \]. \hspace{1cm} (14)

The integration may be terminated at the end of the expansion \((a = a_s)\) or at the end of the acceleration tube, whichever is sooner. If the reflected wave reaches the downstream end of the expansion before it reaches the end of the tube, it continues to propagate into the test flow region (20) with speed \(u_s + a_s\). The time of arrival as computed with this approach closely matches the onset of large-amplitude noise in the exit flow histories and is indicated by an asterisk in the wave diagram (Fig. 4).

A comparison of computed test flow properties with the experimental measurements of Shinn and Miller [3] is shown in Fig. 12. The values are taken from the Pitot histories 150 \(\mu s\) after the passage of the shock. The overall level of the computed wall pressure is a little low, possibly because of the low estimate for the initial temperature in the driver tube. Also, the computed wall pressure is smoother than the experimental wall pressure. This may be partly due to numerical dissipation and partly due to noisy measurement techniques in the experiment. The arrival of the downstream tail of the unsteady expansion can be seen by the rise in pressure 0.2 \(ms\) after the passage of the shock in both the simulation and the experiment.

The other frames in Fig. 12 show Pitot pressures. The computed Pitot pressure at the centreline is again a little lower than the experimental value and is also less noisy for the first 0.4 \(ms\) after shock arrival, possibly due to excessive diffusion in the numerical scheme. However, there is good agreement in that two types of disturbances are evident: a small-amplitude noise before the arrival of the reflected head of the unsteady expansion and a large-amplitude noise after the passage of the reflected expansion. This is one of the main results of this study.

Other features evident in the Pitot histories include the large dip at \(t = 5.0 \, ms\), \(r = 52.5 \, mm\) and the consistently low values at \(r = 71 \, mm\). The large dip is associated with the passage of the bulge in the boundary layer while the \(r = 71 \, mm\) position remains within
the boundary layer after the passage of the test-gas/acceleration-gas interface.

3.3 Case 2: \( P_1 = 20.62 \text{ kPa}, \ P_{10} = 16 \text{ Pa} \)

Having simulated the arrival of noise in the test flow at \( P_1 = 3.45 \text{ kPa} \), it was decided to try a higher pressure of \( P_1 = 20.62 \text{ kPa} \) where the experimental measurements indicated that large-amplitude disturbances appear very early in the test flow. Fig. 13 shows the wave diagram for this case. Note that the downstream tail of the unsteady expansion arrives at the tube exit shortly after the test flow begins and that the reflected head of the unsteady expansion is expected to arrive much later. Because of the higher initial intermediate-tube pressure, the shock has a lower speed than in case 1.

The first frame of Fig. 14 shows the state of the density field just before the rupture of the secondary diaphragm. Transverse waves are still present in the expanded driver gas but they seem to be weaker. Also, there is some noise evident in the compressed test gas. The unsteady expansion of the test gas is shown in sequential frames of Fig. 14. The process appears similar to that in case 1 except that there is very little noise evident in the expanded test gas (even at \( t = 5.0 \text{ ms} \)). This lack of noise is confirmed in Fig. 15. Although perturbations have been introduced at the primary-diaphragm station, the weaker expansion of the driver gas has resulted in a weaker focusing of the noise at the downstream end of the expansion (when compared to that in case 1).

Fig. 16 compares the computed pressures at the exit of the acceleration tube with experimental measurements. The arrival of the downstream-tail of the unsteady expansion can be clearly seen at \( t \approx 4.8 \text{ ms} \) while the reflected head of the unsteady expansion is not expected to arrive at the tube exit until \( t \approx 5.84 \text{ ms} \) (see table 6). The lack of noise in the laminar solution suggests that the disturbances in the experimental test flow are caused by boundary layer transition or turbulence (which is not modelled in these simulations) rather than propagation of noise through the driver-gas/test-gas interface. The omission of
turbulence is a major limitation of this study as the experimental flow is turbulent over most of the high-pressure operating range of the facility.

The average value of the computed Pitot profile (taken 150 $\mu$s after passage of the shock) is again slightly lower than the experimental value, possibly because of the low initial value for the driver gas temperature. The very low Pitot pressure values computed for $r/r_w \approx 0.7$ are the result of taking the value of Pitot pressure in the hot acceleration gas following behind the interface.

3.4 Case 3: $P_1 = 1.74 \text{ kPa}$, $P_{10} = 16 \text{ Pa}$

Given the failure of the $P_1 = 20.62 \text{ kPa}$ case to exhibit large disturbances in the simulated test flow, a case with lower intermediate-tube pressure than case 1 was attempted. Figures 17 - 19 show the results of a simulation with $P_1 = 1.74 \text{ kPa}$, $P_{10} = 16 \text{ Pa}$.

Table 4 shows that the shock speed during the initial compression of the test gas is slightly higher than for case 1 but that the final shock speed during the unsteady expansion process is slightly lower. The shock compression of the test gas appears to be noisier than for case 1 and the centreline histories indicate that small-amplitude disturbances appear very early in the test flow. This seems to be consistent with the experimental Pitot pressure results shown in Fig. 19. The arrival of the reflected head of the unsteady expansion ($t \approx 5.1 \text{ ms}$) is marked with a double asterisk in Fig. 17 and can be seen as a decrease in the growth rate of Pitot pressure in Fig. 19. In the simulation, the arrival of this wave is accompanied by larger-amplitude and higher-frequency disturbances which are not obvious in the experimental measurements. Also, the average value of the computed Pitot pressure across the exit plane is significantly lower than the experimental value.

3.5 Case 4: $P_1 = 3.45 \text{ kPa}$, $P_{10} = 52.6 \text{ Pa}$

For large values of acceleration-tube filling pressures, Shinn and Miller [3] also observed a large dip in the Pitot pressure shortly after the start of the test flow. The phenomenon
was attributed to boundary layer transition. This particular case simulates such an operating condition in order to see if the bulge in the boundary layer (following the test-gas/acceleration-gas contact surface) contributed to the large dip.

The results for the laminar-flow simulation with $P_1 = 3.45 \, kPa$, $P_{10} = 52.6 \, Pa$ are shown in figures 20 - 22. The shock compression phase is the same as for case 1a but, with the larger mass of acceleration gas, the separation distance between the shock and the contact surface is increased and equilibrium is attained by $t = 2.8 \, ms$. The histories of the wall pressure shown in Fig. 22 indicate that small-amplitude noise is present in both the acceleration gas and test gas up until the arrival of the reflected head of the unsteady expansion at $t \simeq 4.9 \, ms$. This event is denoted on the wave diagram (Fig. 20) by a double asterisk. The arrival time, estimated with equations (12) - (14) is denoted by a single asterisk.

Although the large-amplitude noise after the passage of the reflected expansion seems to be consistent with the experimental measurements, there is no evidence of the large Pitot-pressure dip in the laminar simulation. This is consistent with the hypothesis [3] that the dip is caused by boundary layer transition. Note that this case was computed on a coarse mesh which may result in the attenuation of the high-frequency components of the noise.
4 Concluding Remarks

From the computational point of view, it is possible to perform reliable simulations for laminar axisymmetric flow of a perfect gas in an expansion tube over a limited range of operating conditions. Although viscous effects are adequately resolved in the acceleration tube, they were not well resolved in either the intermediate tube or the driver tube. This is not considered to be a major problem as inviscid multidimensional flow features seem to dominate the performance of the driver and intermediate sections of the facility.

The numerical technique is capable of capturing strong shocks and contact surfaces with large temperature jumps, however the contact surfaces tend to be more (numerically) smeared than the shocks. The result is that the estimates of wave propagation times and test flow properties appear to be in reasonable agreement with experimental measurements. However, the issue of reliably capturing the high-frequency noise is not fully settled and further computational experiments using alternative higher-order schemes (such as ENO [15]) are required.

A laminar perfect-gas flow was deliberately selected to keep this study manageable, however, there is an immediate need to perform simulations with nonideal thermal and chemical effects with turbulence in three-dimensions. Diaphragm dynamics is another important item which needs to be considered for future study. In the near future, it is unlikely that all of these features could be included but the modelling of turbulence and the diaphragm dynamics are key items required to simulate the expansion tube over a larger range of useful operating conditions.

With respect to facility design and operation, the simulations show some important features. Firstly, the discontinuity at the primary diaphragm station is sufficient to produce disturbances which may then propagate into the test flow. Secondly, the simulations clearly identify two categories of noise in the test flow. One is a small-amplitude, low-frequency disturbance which may be seen before the arrival of the reflected head of the unsteady
expansion while the other is a large-amplitude, high-frequency noise associated with the passage of the reflected expansion.

This distinction explains the experimental observation [4, 5] that increasing the acceleration-tube pressure \( P_{10} \) while keeping the intermediate-tube pressure \( P_1 \) constant results in higher amplitude and higher frequency noise in the test flow. The increase in \( P_{10} \) results in a lower shock speed in the acceleration tube, while the fixed \( P_1 \) means that the arrival time of the reflected expansion will be essentially constant. Thus, at high values of \( P_{10} \), the reflected expansion is expected to arrive very soon after the shock and introduce high-frequency disturbances to the test flow.

To avoid the large-amplitude noise, it should be relatively simple to select operating conditions or facility configurations which delay the arrival of the reflected expansion. For example, the intermediate tube could be lengthened while fixing the initial gas pressures.

It is not immediately obvious how to avoid the small-amplitude disturbances observed before the arrival of the unsteady expansion. As can be seen in Fig. 23 these disturbances do not appear in the test flow for all operating conditions. The acoustic theory of Paull provides some guide to the correct selection of good operating conditions. The basic results of that theory are that broad-band noise is focussed to a particular frequency across strong expansions and that noise crossing the driver-gas/test-gas interface is attenuated if the speed of sound in the test gas is much higher than the speed of sound in the driver gas. Both of these effects were observed in the simulations. The stronger driver-gas expansions in cases 1, 3 and 4 produced significant disturbances in the expanded driver gas while the jumps in sound speed across the driver-gas/test-gas interfaces attenuated the noise admitted to the expanding test gas.

13. ABSTRACT

Several numerical simulations of the transient flow of helium in an expansion tube are presented in an effort to identify some of the basic mechanisms that cause the noisy test flows seen in experiments. The calculations were performed with an axisymmetric Navier-Stokes code based on a finite-volume formulation and upwinding techniques. Although laminar flow and ideal bursting of the diaphragms was assumed, the simulations showed some of the important features seen in the experiments. In particular, the discontinuity in tube diameter at the primary diaphragm station introduced a transverse perturbation to the expanding driver gas and this perturbation was seen to propagate into the test gas under some flow conditions. The disturbances seen in the test flow can be characterized as either small-amplitude, low-frequency noise possibly introduced during shock compression or large-amplitude, high-frequency noise associated with the passage of the reflected head of the unsteady expansion.
