Abstract

We devise a class of fast wavelet based algorithms for linear evolution equations whose coefficients are time independent. The method draws on the work of Beylkin, Coifman, and Rokhlin [1] which they applied to general Calderon-Zygmund type integral operators. We apply a modification of their idea to linear hyperbolic and parabolic equations, with spatially varying coefficients. A significant speedup over standard methods is obtained when applied to hyperbolic equations in one space dimension and parabolic equations in multidimensions.

\textsuperscript{1}This research was supported by the National Aeronautics and Space Administration under NASA Contract No. NAS1-18605 while the author was in residence at the Institute for Computer Applications in Science and Engineering (ICASE), NASA Langley Research Center, Hampton, VA 23665. Additional support was also provided under ONR Grant No. N00014-91-J-1034.
1. Introduction

During the last few years a number of fast computational algorithms have been developed for elliptic problems. These are techniques for which the number of arithmetic operations needed are close to linear as a function of the number of unknowns. Examples of algorithms of such complexity are multigrid methods and the so-called fast Poisson solvers. The fast multipole method and wavelet based methods for elliptic problems formulated as integral equations also belong to this category [8], [1].

There has not been the same progress for hyperbolic and parabolic methods. In general classical numerical techniques for these problems are already optimal.

Consider a system of evolution equations.

\[ \partial_t u + L(x, \partial_x)u = f(x), \quad x \in \Omega \subset \mathbb{R}^d, \quad t > 0, \]
\[ u(x, 0) = u_0(x), \]

with boundary conditions, where \( L \) is a differential operator.

An explicit discretization of this problem typically takes the form,

\[ u^n_j = u(x_j, t_n), \quad t_n = n\Delta t, \]
\[ x_j = (j_1 \Delta x_1, \ldots, j_d \Delta x_d) \]
\[ u^{n+1} = Au^n + F, \]
\[ u^0 = u_0, \]
\[ u, F \in \mathbb{R}^{Nd}, \quad \Delta t = \text{const.} \ |\Delta x|^{\nu}. \]

The vector \( u^n \) contains all the unknowns \( u^n_j \) at time level \( t_n \). For simplicity we shall assume \( j_\nu = 1, 2, \ldots, N \) in all dimensions \( \nu = 1, \ldots, d \).

The matrix \( A \) is \( (Nd \times Nd) \) with the number of elements \( \neq 0 \) in each row and each column bounded by a constant. Every time step requires \( O(N^d) \) arithmetic operations and the overall complexity for a time interval of \( O(1) \) is of the same order as the number of unknowns, \( O(N^{d+r}) \).

There are, however, some fast methods based on the analytic form of the solution operator. In [3] the multidimensional heat operator, with \( u_0 \) and \( f \) both zero, but with inhomogeneous boundary data given at \( M \) points, was treated. There the closed form of the solution evaluated at \( M \) points at time level \( N \) was obtained in \( O(NM) \) rather than \( O(N^2M^2) \) operations. Also, in [4], the same authors obtained an algorithm for evaluating the sum of \( N \) Gaussians at \( M \) arbitrarily distributed points in \( O(N + M) \) operations. So far, their
interesting method appears to need an explicit analytic representation of the heat kernel, effectively ruling out variable coefficient problems.

The formula (1.2) has a simple closed form solution

\[ u^n = A^n u_0 + \sum_{\nu=0}^{n-1} A^\nu F. \]

This form can be used to compute the solution \( A^n u_0 \), for \( F = 0 \), in \( \log n \) steps, \( (n = 2^m, m \) integer; here and throughout, \( \log n = \log_2 n \)) by repeated squaring of \( A : A, A^2, A^4, A^8, \ldots, A^{2^m} \).

Unfortunately the later squarings involve almost dense matrices and the overall complexity is \( O(N^{3d} \log N) \) which is larger than that using (1.2) directly.

For an appropriate representation of \( A \) in a wavelet basis all of the powers \( A^\nu \) may be approximated by sparse matrices and the algorithm using repeated squaring should then be advantageous.

We shall consider the following algorithms for the computation of the closed form solution (1.3) of the inhomogeneous problem in \( m = \log n \) steps,

\[
\begin{align*}
B &:= SAS^{-1} \\
C &:= I \\
C &:= TRUNC(C + BC, \varepsilon) \\
B &:= TRUNC(BB, \varepsilon) \\
u^n &:= S^{-1}(BSu^0 + CSF).
\end{align*}
\] (iterate \( m \) steps)

The matrix \( S \) corresponds to a fast transform of wavelet type and the truncation operator sets elements in a matrix to zero if their absolute value is below a given threshold.

\[
\tilde{A} = TRUNC(A, \varepsilon) : \begin{cases} 
\tilde{a}_{ij} = a_{ij} & |a_{ij}| \geq \varepsilon \\
\tilde{a}_{ij} = 0 & |a_{ij}| < \varepsilon.
\end{cases}
\]

It is easy to see that algorithm (1.4) is equivalent to (1.3) for \( \varepsilon = 0 \). This is not so for \( \varepsilon > 0 \) and also for \( F \neq 0 \). We shall however show that it is possible to choose \( \varepsilon \) small enough for the result of (1.4) to be arbitrarily close to (1.3) but still with very few arithmetic operations.

For a fixed predetermined accuracy level the computational complexity to calculate a one dimensional hyperbolic equation can be reduced from the standard \( O(N^2) \) to \( O(N(\log N)^2) \). The extra cost per time step is minimal. This also makes it possible, as a curiosity, to use algorithms which are unstable in the traditional sense.

Our technique is even more favorable for parabolic problems. A \( d \)-dimensional explicit calculation with standard complexity \( O(N^{d+2}) \) may be reduced to \( O(N^d(\log N)^3) \).
The algorithm (1.4) can be extended to some problems with time dependent data. In this case, we clearly need to compress the information in the data such that not all the $O(N^{d+r})$ values in, e.g. the inhomogeneous term $f(x_j, t_n)$ are needed.

One simple but important application of this type is from optics or electro-magnetic scattering with a time periodic source. If $k$ points are needed to resolve one time period, we can group $k$ time steps together

$$(1.6a) \quad u^{n+k} = A^k u^n + \sum_{j=0}^{k-1} A^j F_{n+k+j-1}.$$

where

$$(1.6b) \quad F_n = \Delta t f(t_n).$$

This equation is now of the type (1.2) with time step $k\Delta t$ and with inhomogeneous term

$$(1.6c) \quad F = \sum_{j=0}^{k-1} A^j F_{n+k+j-1}.$$

In sections 2 and 3 we shall discuss the analytical properties of the algorithm. Numerical examples are presented in section 4.

2. Hyperbolic Problems

Consider first the simple one dimensional scalar advection equation,

$$\partial_t u + a \partial_x u = 0, \quad a > 0$$

$$(2.1) \quad u(x, 0) = u_0(x), \quad 0 \leq x \leq 1.$$  

The functions $u_0$ and thus $u$ are assumed to be 1-periodic in $x$. The solution of (2.1) is given by:

$$(2.2) \quad u(x, t) = u_0(x - at).$$

The different rows of $A^r$ in a numerical solution of (2.10) will represent approximations of the Green's function $G$ below,

$$u(x, t) = \int_{-\infty}^{\infty} G(x, y, t) u_0(y) dy,$$

$$(2.3) \quad u(x, t) = \int_{-\infty}^{\infty} \delta(x - y - at) u_0(y) dy.$$
Let \( \varphi_J \) be a truncated wavelet expansion of a \( \delta \)-function with an orthonormal set of compactly supported wavelets,
\[
\delta(x) \sim \varphi_J(x) = \sum \alpha_{jk} \varphi_{jk}(x)
\]
\[
\varphi_{jk}(x) = 2^{-\frac{j}{2}} \psi(2^{-j} x - k + 1)
\]
The choices of \( \psi(x) \) will be discussed below. Assume that the rows of \( A^\nu \) are discrete \( \delta \)-functions, i.e. just one element is nonzero and large. For each level \( j = 1, 2, \ldots, J \) there are only a finite number of \( \alpha_{jk} \neq 0 \). With \( J = m = \log N \) there is only \( \log N \) of all \( \alpha_{jk} \neq 0 \). Thus each row in \( B, (1.4) \), has \( \log N \) elements, \( b_{jk} \neq 0 \). The matrix \( B^2 \) is also a transform of an idealized matrix \( A^\nu \) and will have \( N \log N \) elements different from zero. This means that each iteration step in the algorithm (1.4) produces \( O(N(\log N)^2) \) flops when \( F = 0 \).

We have assumed that calculations are only carried out for those \( B^2 \) elements which are different from zero. In practice a slightly larger number of elements needs to be computed and then truncated. This corresponds to the case when the location of the \( \delta \)-functions is only approximately known. Compare the wavelet technique for Burgers’ equation by Maday, Perrier, and Ravel [6].

Each row of \( C, (1.4) \), is a transform of a step function,
\[
\tilde{c}(x) = \begin{cases} 
\text{const.} & 0 \leq x \leq at, \\
0, & \text{else}
\end{cases}
\]
This function can also be represented by \( \log N \) wavelets and thus the overall cost is \( O(N(\log N)^3) \).

In numerical computations the rows of \( A^\nu \) are only approximations of \( \delta \)-functions. If an upwind scheme,
\[
u_j^{n+1} = u_j^n - \lambda(u_j^n - u_{j-1}^n),
\]
(2.4)
\[
u_j^0 = u_0(x_j), \quad j = 1, 2, \ldots N,
\]
\[
\lambda = a\Delta t/\Delta x < 1,
\]
is used \( A \) will have the form,
\[
A = \begin{bmatrix}
1 - \lambda & 0 & \cdots & \lambda \\
\lambda & 1 - \lambda & 0 & \cdots & 0 \\
0 & \lambda & 1 - \lambda & 0 & \cdots & 0 \\
& \cdots & & & \lambda & 1 - \lambda
\end{bmatrix}.
\]
The matrix \( A^\nu \) will have Toeplitz structure. Each row is still an approximation of a \( \delta \)-function. The first order smoothing effect of (2.4) is given by the modified equation, [5],
\[
\partial_t u + a \partial_u u = (a\Delta x/2)\partial_x^2 u.
\]
(2.5)
Equation (2.5) is parabolic with a fundamental solution of the form,

\begin{equation}
G(x - y, t) = (2\pi a\Delta x t)^{-\frac{1}{2}} \exp(-(x - y - at)^2/(2a\Delta x t)).
\end{equation}

Compare the solution formula for parabolic problems (3.2).

Each row of $A^\nu$ is thus a close approximation to the function $G(x - y, t)$ above. The computational complexity of the algorithm (1.4) depends on how many wavelets are needed to represent $G(x - y, t)$ as a function of $x, (0 \leq t \leq T)$ with a given accuracy.

Higher order accurate (say order 2p-1) dissipative finite difference approximations to (2.1) are usually modelled by the equation

\begin{equation}
 u_t + au_x = (-1)^{p+1}k_p(\Delta x)^{2p-1} \left( \frac{\partial}{\partial x} \right)^{2p} u.
\end{equation}

with $k_p \geq \delta > 0, \delta$, independent of $\Delta x$.

The fundamental solution for this parabolic equation is:

\[ G_p(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\xi \exp(i\xi(x - at) - k_p(\Delta x)^{2p-1}\xi^{2p}t)). \]

The key estimate we shall obtain here (and which we certainly do not claim is new) is:

\begin{equation}
 x^{m+1} \left( \frac{\partial}{\partial x} \right)^m G_p(x + at, t) \leq C_{m,p}
\end{equation}

uniformly in $0 < t$ and $\Delta x$ and for all nonnegative integers $m$.

**Proof of 2.8.** We wish to bound

\[
\frac{1}{2\pi} \int_{-\infty}^{\infty} (i\xi)^m x^{m+1} e^{i\xi(x - k_p(\Delta x)^{2p-1}\xi^{2p}d\xi.}
\]

\[
= \frac{i}{2\pi} \int_{-\infty}^{\infty} e^{i\xi x} \left( \frac{\partial}{\partial \xi} \right)^{m+1} \left[ \xi^m e^{-k_p(\Delta x)^{2p-1}\xi^{2p}t} \right] d\xi
\]

\[
= \frac{i}{2\pi} \int_{-\infty}^{\infty} \exp \left( \frac{i\xi x}{(t(\Delta x)^{2p-1}k_p)^{1/2p}} \right) \left[ \left( \frac{\partial}{\partial \xi} \right)^{m+1} \left[ \xi^m e^{-\xi^{2p}} \right] \right] d\xi.
\]

The result is now clear. Also, an inspection of the right hand side of the above shows that $C_{m,p}$ can be chosen to be arbitrarily small if $t(\Delta x)^{2p-1}$ is large enough.

**Remark R1.** Let the general space dependent coefficient, one dimensional system of hyperbolic equations

\[ u_t + A(x)u_x = C(x)u, \]
where $u$ is an $\ell$ vector, $A$ is a uniformly diagonalizable smooth $\ell \times \ell$ matrix, with all real
eigenvalues $\lambda_i(x)$, and $C(x)$ is smooth, be approximated by a dissipative finite difference
scheme of order $2p - 1$. Typically, its model equation is a systems version of (2.1)

$$u_t + A(x)u_x = C(x)u + (-1)^{p+1}(\Delta x)^{2p-1}P \left( x, \frac{\partial}{\partial x} \right) u$$

where $(-1)^{p+1}P(x, \frac{\partial}{\partial x})$ is a $2p$ order elliptic operator. A more involved argument shows that
the fundamental solution satisfies an estimate of the type (2.8) with the expression $x + at$
replaced appropriately by solutions of $\frac{d\xi}{dt} = \lambda_i(\xi)$ $\xi(0) = x, \quad i = 1, \ldots, \ell$ and with $C_{m,x}$
possibly growing in time like $C_{m,x}e^{kt}$ for $k$ fixed.

Our numerical procedure involves the compression of the matrix $A^\nu$, which for the purpose
of analysis only, we shall view as the discretization of the fundamental solution for either
(2.5) or (2.7),

$$(A^\nu)_{jk} = G(x_j, y_k, t^n)$$

where the interval $[0, 1]$ is discretized via

$$x_j = \frac{j}{N}, \quad j = 1, \ldots, N, \quad N = 2^\nu,$$

$[0, 1] \times [0, 1]$ is discretized via $(x_j, y_k)$, and $t^n = n\Delta t = n\lambda\Delta x, \quad n = 0, 1, \ldots$.

We now adapt the terminology, notation, and results of [1] to this unsteady problem
(1.1).

Finite difference schemes approximating (1.1), e.g. (2.4) are regarded as acting
on a vector $\{s_k^0\}_{k=1}^N$ which is to be viewed as approximating $u(x, 0)$ on the finest scale:

$$s_k^0 = 2^k \int \varphi(2^\nu x - k + 1)u(x, 0)dx$$

$$= \int f(x)\varphi_{\nu k}(x)dx.$$

All functions, both continuous and discrete, are extended periodically:

$$u(x, t) \equiv u(x + 1, t)$$

$$s_{k+N}^0 \equiv s_k^0$$

etc.

The function $\varphi$ satisfies

$$\varphi(x) = \sum_{p=0}^{2m-1} h_{p+1}\varphi(2x - p)$$

The function $\psi(x)$ which will generate an orthonormal basis is obtained via

$$\psi(x) = \sum_{p=0}^{2m-1} g_{p+1}\varphi(2x - p)$$
with \( g_p = (-1)^{p-1} h_{2m-p+1}, \ p = 1, \ldots, 2m \) and \( \int \varphi(x)dx = 1. \)

The coefficients \( \{h_p\}_{p=1}^{2m} \) are generally chosen so that
\[
\psi_{j,k}(x) = 2^{-j} \varphi(2^{-j} x - k + 1),
\]
for \( j, k \) integers, form an orthonormal basis and in addition, the function \( \psi(x) \) has \( m \) vanishing moments
\[
\int \psi(x)x^\ell dx = 0, \ \ell = 0, 1, \ldots, m - 1.
\]

Also we define
\[
\varphi_{j,k} = 2^{-j} \varphi(2^{-j} x - k + 1).
\]

Finally, we assume that there exists a real constant \( \tau_m(\tau_1 = \frac{1}{2}) \) such that the following conditions are satisfied:
\[
\int \varphi(x + \tau_m)x^\ell dx = 0 \quad \text{for} \quad \ell = 1, \ldots, m - 1,
\]
and \( \int \varphi(x)dx = 1. \)

In this case the quadrature formula becomes:
\[
s_k^0 = \frac{1}{\sqrt{N}}(f(k - 1 + \tau_m) + O(N^{-(m+1)}))
\]
and the initial discretization error is \( O(N^{-(m+1)}) \) up to uniform translation.

The decomposition of the vector \( \{s_0^0, \ldots, s_{2^\nu}^0\} \) into the basis we use to compute with comes via
\[
\{s_k^0\} \rightarrow \{s_k^1\} \rightarrow \{s_k^2\} \rightarrow \cdots \rightarrow \{s_k^n\}
\]
and the \( s_k^i, d_k^i \) are viewed as periodic sequences with period \( 2^{\nu-i} \).

The orthonormal basis consists of
\[
[d_1^1, \ldots, d_{2^j}^1, d_1^2, \ldots d_{2^j}^2, \ldots, d_n^n, s_1^n].
\]

The inverse mapping can also be done in \( O(N) \) operations.
Each of the $s^i_k$ is thought of as approximating

$$s^i_k = \int f(x)\varphi_{jk}(x)dx = 2^{-\left(\frac{\nu+1}{2}\right)}\left[f(2^{-\nu+j}(k-1 + \tau_m))ight] + O(N(-\nu+j)(m+1))$$

while each $d^i_k$ is thought of as approximating

$$d^i_k = \int f(x)\psi_{jk}(x)dx.$$

The numerical procedure effectively transforms the approximate discretization of the matrix $G(x_j, y_k, t^n)$ which is $(A^n)_{jk}$. Estimate (2.8) (corresponding to (4.5) and (4.6) of [1], uniform in all parameters, indicates (via an argument of [1]) that truncating $A^n$ by removing elements of a band of width $b \geq 2m$ around a shifted diagonal (and its periodic extension) i.e., those for which

$$|j - k - a\lambda n| \geq b > 2m,$$

which replaces $A^n$ by $A^{n,b}$, leads to an estimate

$$\|A^n - A^{n,b}\| \leq \frac{C}{b^m} \log(N)$$

for $C$ depending only on $G$.

It also follows easily that for large $N$ and fixed precision $\varepsilon$, only $O(N \log N)$ elements will be greater than $\varepsilon$. Alternatively, by discarding all elements that are smaller than a fixed threshold we compress it to $O(N \log N)$ elements. Again following the discussion in [1], we note that this naive approach is to construct the full matrix in the wavelet basis and then to threshold. Clearly this is an $O(N^2)$ operation.

Since we have, à priori, the structure of the singularities of the matrix $A^n$ the relevant coefficients can be evaluated by using the quadrature formulas. Estimate (2.8) guarantees that this procedure requires $O(N \log N)$ operations.

**Remark R2.** It is interesting to note that so called unstable difference schemes can be used without any drastic loss of efficiency. If (2.1) is approximated by,

$$u^n_{j+1} = u^n_n - \lambda(u^n_{j+1} - u^n_{j-1})/2,$$

(2.9)

$$u^n_0 = u_0(x_j), \quad j = 1, 2, \ldots, N$$

the algorithm is not stable for any fixed $\lambda > 0$, see e.g. [7].
The approximation does converge if $\Delta t \leq C \Delta x^2$, $(\lambda \leq C \Delta x)$ with an amplification factor $1 + O(\Delta t)$. The number of timesteps for $t = O(1)$ calculation will be large, $n = O(\Delta x^{-2}) = O(N^2)$. This is devastating for the standard explicit algorithm (1.2) but will only affect the complexity of (1.4) by a constant factor. The number of iterations ($m$ in (1.4)) will increase from $\log(N)$ to $\log(N^2)$.

Our approach is in general not as favorable for multidimensional hyperbolic systems,

$$
\partial_t u + \sum_{j=1}^{d} A_j(x) \partial_{x_j} u = f(x), \quad x \in \mathbb{R}^d,
$$

(2.10)

$$u(x, 0) = u_0(x).$$

When $u$ is a scalar or if the system can be diagonalized the algorithm (1.4) works well. The solution is given by integration along characteristics and the support of the Green's function is a small number of points (see Remark (R1) above). In the idealized case each row of $A^\nu$ consists of a fixed number of $\delta$-functions. Its wavelet representation will have $\log(N^d)$ nonzero terms. The overall complexity for (1.4) is then $O((\log N)^3 N^d)$ when the knowledge of the location of the $\delta$-functions is used. This is better than the standard $O(N^{d+1})$ estimate.

In general, however, the Green's function for (2.6) has a support with positive volume in $\mathbb{R}^d$ and with a singular support of positive measure in Hausdorff dimension $d - 1$. The representation of the singular support consists of $O(N^{d-1})\delta$-functions in each row of $A^\nu$. This corresponds to $O((\log N)N^{d-1})$ wavelets and the overall algorithm contains at least $O((\log N)^2 N^{2d-1})$ wavelets.

For general multidimensional problems the new algorithm is still of interest in special cases, e.g., if the solution is needed only at a fixed number of points and if it is needed for a large number of different data $u_0, f$.

3. Parabolic Problems

The Green's function for parabolic problems is smooth in contrast to the hyperbolic case. The pure initial value problem for the heat equation,

$$
\partial_t u = \Delta u, \quad t > 0, \quad x \in \mathbb{R}^d,
$$

(3.1)

$$u(x, 0) = u_0(x),$$

has a solution of the form,

$$u(x, t) = (4\pi t)^{-d/2} \int_{\mathbb{R}^d} \exp(-|x - y|^2/4t)u_0(y)dy.$$

(3.2)
In bounded domains the kernel has to be changed slightly depending on the boundary conditions. For positive \( t(= n\Delta t) \) each row in \( A^n \) is always an approximation of segments of regular functions.

Our new technique is in general more favorable for parabolic problems than hyperbolic ones. The structure of the matrix \( B \) in (1.4) is simpler. When \( t \) increases the kernel becomes smoother and \( \alpha_{jk} \) can be truncated to zero for all \( k \) when \( j \) is large enough.

Explicit methods for (3.1) also requires more operations than for hyperbolic problems when the standard method is used. This follows from the parabolic stability requirement,

\[
\Delta t \leq \text{const. } |\Delta x|^2.
\]

The new technique is only marginally affected by the constraint (3.3). Compare here the discussion above for unstable hyperbolic methods.

In more general higher order multidimensional parabolic cases the fundamental solution of, e.g.,

\[
u_t + (-\Delta)^4 u = 0
\]

is

\[
G_d(x, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\xi \exp(i\xi \cdot x - |\xi|^{2d}t).
\]

This is merely a multidimensional and rescaled version of the fundamental solution used in (2.8), and a simpler, but multidimensional version of (2.8) is just:

\[
\left| |x|^{m+1} D_x^m G_d(x, t) \right| \leq C_{md}.
\]

Moreover \( C_{md} \) is arbitrarily small if \( t \) is large enough (this of course requires the nonexistence or other special behavior of lower order terms).

The matrix compression technique is easy here (for periodic problems without boundary conditions) because the significant terms of \([A^n]\) lie near the main diagonal and its periodic extension in one dimension. In two space dimensions (as is usual for elliptic operators), we also need to consider diagonals \( i = j \pm kN \) for \( 0 < k \leq d \). Recall \( A \) is an \( N^2 \times N^2 \) matrix in 2D.

It is clear that à priori thresholding (to obtain \( O(\varepsilon) \) precision) near the image of these diagonals will give us an \( O(N^d(\log N)^3) \) operation for each evaluation of the solution, where \( d \) is the number of space dimensions for the problem.

4. Numerical Experiments

The algorithm (1.4) was applied to hyperbolic problems in one space dimensions and to one and two dimensional parabolic problems. Various difference approximations and wavelet
spaces were used. We present results concerning the accuracy of the calculations and the sparsity of \((SAS^{-1})^n\).

**4.1 Hyperbolic problems.** Consider the following scalar hyperbolic problem:

\[
\begin{align*}
\partial_t u + a(x)\partial_x u &= f(x) \\
u(x,0) &= u_0(x)
\end{align*}
\]

(4.1a)

with periodic boundary conditions \((0 \leq x \leq 1)\). We made the following choices:

(4.1b) \(a(x) = 0.5 + 0.115\sin(4\pi x)\)

(4.1c) \(f(x) = \cos(4\pi x)\)

(4.1d) \(u_0(x) = \sin(4\pi x)\).

In the discretization, \(\Delta x = 1/1024\) and \(\Delta t/\Delta x = 1\). The wavelet transform operator \(S\) uses the Daubechies-8 wavelets, which have 8 coefficients and have 4 vanishing moments. Finite difference schemes of order 1, 2, 3, 4, and 5 of accuracy are tested.

These finite difference schemes are obtained as follows. In each interval 

\[
I_{\nu-\frac{1}{2}} = \{x/(\nu - 1)\Delta x \leq x \leq \nu\Delta x\}
\]

(4.2)

a polynomial of degree \(k\) is constructed. This polynomial interpolates the two points \((x_{\nu-1}, u_{\nu-1}^n)\) and \((x_{\nu}, u_{\nu}^n)\) and \(k - 1\) of its neighbors. If \(k\) is even these interpolation points go from \(x_{\nu-\frac{1}{2}}\) to \(x_{\nu+\frac{1}{2}}\). If \(k\) is odd they go from \(x_{\nu-(\frac{k-1}{2})}\) to \(x_{\nu+(\frac{k-1}{2})}\). This gives us a reconstruction function which is a polynomial of degree \(k\) in each \(I_{\nu-\frac{1}{2}}\) and is continuous, but generally not differentiable at the boundary points \(x_{\nu-1}\) and \(x_{\nu}\). We call this function \(R_{n,k}(x)\)

To approximate (4.1) at the grid points \((x_{\nu}, t^{n+1})\) we solve (4.1) “exactly” with initial data

\[
u_{\Delta x}(x, t^n) = R_{n,k}(x)
\]

(4.3)

for \(t^n \leq t \leq t^{n+1}\), evaluate the solution at \((x_{\nu}, t^{n+1})\), and set \(u_{\nu}^{n+1} = u_{\Delta x}(x_{\nu}, t^{n+1})\). We require \(\Delta t \leq \text{max}\{|a(x)| \leq 1\}/\Delta x\), so the solution depends only on data in \(I_{\nu-\frac{1}{2}}\) if \(a(x) > 0\) and \(I_{\nu+\frac{1}{2}}\) if \(a(x) < 0\).
In the special case when \( a(x) = a \), constant, then
\[
\begin{align*}
u^n + 1 &= R^n, k(x) - a \Delta t) \\
\end{align*}
(4.4)
\[
+ \int_{t^n}^{t_n+1} f(x(t) - a(t^n - s)) ds
\]

In the case when \( f \equiv 0 \) we get some familiar schemes: For \( k = 1 \) this is just the first order accurate upwind difference scheme (2.4). For \( k = 2 \) this is just the classical Lax-Wendroff second order accurate three point scheme, see e.g. [7]. For \( k = 3, 4, 5 \) the schemes are less studied, but are known to be \( L^2 \) stable, see e.g. [9] and the references therein.

For variable coefficients the result is
\[
\begin{align*}
u^n + 1 &= R^n, k(x(t^n)) \\
\end{align*}
(4.5a)
\[
+ \int_{t^n}^{t_n+1} f(x(t^n - s)) ds
\]

where \( x(t) \) solves
\[
\frac{dx}{dt} = a(x), \quad t^n \leq t \leq t_n+1
(4.5b)
\]
\[
x(t_n+1) = x_n.
(4.5c)
\]

A fourth order Runge-Kutta method is used to integrate the O.D.E. (4.5b,c) and Simpson's rule is used to evaluate the integral in (4.5a). The result of this approximation to the right side of (4.5a) is defined to be \( u^n + 1 \).

Returning to the present case the computations ran 13 steps until \( t = 4 \), that is, \((SAS)^{-1} 2^{13}\) was computed.

At each step \( n \) the number of elements of \( A^n \) and \((SAS)^{-1} n\) whose absolute values are greater than \( 10^{-4} \) is shown in table 1. This is for methods whose order of accuracies go from one through five. The results are also plotted on Figure 1.

These significant elements are located near the sub-diagonal corresponding to the characteristic curve which is known a priori. The image of these locations in \((SAS)^{-1} n\), shown on figure 2, has total length of \( O(N \log N) \) elements where \( N = 1024 \).

In the computation of \((SAS)^{-1} n\), first, from the knowledge of the PDE, we figure out the structure of the singularities of \( A \) and its image in \((SAS)^{-1} n\). Then we compute \((SAS)^{-1} 2n = (SAS)^{-1} n * (SAS)^{-1} n\) considering only the elements in a neighborhood of the singularities. In particular, we define the neighborhood of a singularity to be locations whose distance from the singularity are less than or equal to 5. If the singularities lie on a subdiagonal and its periodic extension its neighborhood form a subband of bandwidth 11 (the wavelet filters
have 8 elements). This bandwidth is independent of the time $t$ (the step $n$) and the size of the problem. The errors due to the subband truncation, measured by $\|u^n - \tilde{u}^n\|/\|u^n\|$, are shown in table 2b. Table 2a shows the relative error between the subband truncation and the exact solution. Here and throughout, "$\| \cdot \|$" denotes the $\ell^2$ norm. Table 2c shows the relative error between the subband truncation and untruncated under grid refinement for the various orders. Unsurprisingly, since the relative length of the subband which is preserved decreases linearly with grid size, the error increases, but only slightly under this process.

We note that the compression (as seen in Figure 1 and Table 1) is better for odd order than for even order schemes. This is perhaps not surprising since (2.7) models schemes of odd order accuracy. Singularities behave a bit differently for even order (say order = $2p$) schemes. Singularities behave a bit differently for odd order (say order = $2p$) schemes. These are modeled by

$$u_t + au_x = \ell_p(\Delta x)^{2p} \left( \frac{\partial}{\partial x} \right)^{2p+1} u$$

$$+ (-1)^p k_p(\Delta x)^{2p+1} \left( \frac{\partial}{\partial x} \right)^{2p+2} u$$

where $k_p > 0$ and $\ell_p$ are nonzero constants. The odd order dispersive term above may tend to spread singularities of the fundamental solution spuriously.

Finally table 3 shows the relative error due to truncation when the bandwidth of the subband is 9, 11, and 13 for the methods of first and second order. Figures 3a and 3b compare the truncated versus the approximate solutions due to truncation of bandwidth 9 for the first and second order methods (the truncated graphs are dotted).

4.2 Unstable Schemes. For theoretical interest, we apply the method to a finite difference scheme which is unstable for $\frac{\Delta t}{\Delta x} = \lambda > 0$

$$u_j^{n+1} = u_j^n - \lambda (u_{j+1}^n - u_{j-1}^n)/2,$$

$$u_j^0 = u_0(x_j).$$

The amplification factor of this scheme is

$$1 - \lambda \sin \theta = r(e^{i\theta}), \quad -\pi < \theta \leq 1$$

so

$$|r(e^{i\theta})| = (1 + \lambda^2 \sin^2 \theta)^{\frac{1}{2}}.$$

This means that if

$$\Delta t \leq 2c(\Delta x)^2$$
for some $c > 0$, then

\[(4.10) \quad \|A^n\|_{\infty} \leq e^{cn\Delta t}.\]

The restriction (4.9) means that the operation count for this explicit method would be $O(N^3)$ if we were silly enough to use it. However our compression method allows for an operation count of $O(N(\log N)^3)$ for the reasons described above.

Table 4 shows the number of elements in $A^n$ and $(SAS^{-1})^n$ whose absolute values are greater than $10^{-3}$. We choose a bigger threshold here since we took $\frac{\Delta t}{(\Delta x)^2} = 1$ and $n\Delta t = 2$, so $\|A^n\|$, as estimated in (4.10) grows to be roughly 10 when we are finished computing.

The error as measured by $\|v^n - u^n\|_{1}$ (subband truncation using bandwidth 11) was 0.0136.

We also performed convergence studies as we refined the grid for this method. Figures (4a,b,c) compare the numerical (untruncated) using dots versus exact solution for $m = 128, 256, 512$ grid points. The result indicates a second order method, as it should, since $\Delta t = (\Delta x)^2$. Figures (5a,b,c) compare the truncated bandwidth (using dots) vs the untruncated for this method for $m \neq 128, 256$, and 512 grid points.

The relative error decreases with mesh refinement. The truncation error equation associated with this scheme involves limited antidiffusion. Perhaps this accounts for this behavior.

4.3 System of Hyperbolic Equations. We apply the method to solving the system of hyperbolic equations:

\[(4.11a) \quad \partial_t \begin{bmatrix} v \\ w \end{bmatrix} + \begin{bmatrix} a & 0 \\ 0 & -a \end{bmatrix} \partial_x \begin{bmatrix} v \\ w \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},\]

on $0 \leq x \leq 1, t \geq 0$ with the boundary conditions and initial conditions:

\[v(0, t) = w(0, t) \]
\[w(1, t) = v(1, t) \]

\[(4.11b) \quad v(x, 0) = v_0(x) \]
\[w(x, 0) = w_0(x) \]

the coefficient $a$ is chosen to be constant:

\[a = 0.115.\]

The numerical method used is the first order accurate upwind method described above. The results are similar to the scalar case, except the structure of the singularities in the matrices is more complicated. We have to keep track of reflections of singularities at the
boundaries which is quite simple in this case. The number of elements in $A^n$ and $(SAS^{-1})^n$ whose absolute values are greater than $10^{-4}$ is shown on table 5, and is plotted on figure 6. The relative error due to the subband of width 11 truncation, measured by $\|u^n - \tilde{u}^n\|/\|u^n\|$, is 0.0149.

The structure of the elements whose absolute values are greater than $10^{-4}$ of $A^{2048}$ and $(SAS^{-1})^{2048}$ is shown in figures (7a,c), while Figure (7b) shows the image of a subband of bandwidth 11 in $(SAS^{-1})^{2048}$.

4.4 Parabolic Problems. We do experiments on the following parabolic problem:

$$\begin{align*}
\partial_t u &= \partial_x(a(x)\partial_x u) + f(x) \\
u(x, 0) &= u_0(x)
\end{align*}$$

(4.12)

with periodic boundary conditions ($0 \leq x \leq 1$). We made the following choices:

$$\begin{align*}
a(x) &= 0.5 + 0.25 \sin(2\pi x) \\
f(x) &= -\pi^2 \cos(2\pi x)^2 + \pi^2(0.5 + 0.25 \sin(2\pi x)) \sin(2\pi x) \\
u_0(x) &= \sin(4\pi x).
\end{align*}$$

The discrete setting and the wavelets are the same as in the hyperbolic problem. We use the simple explicit central difference scheme (4.13)

$$\begin{align*}
u_j^{n+1} &= u_j^n + \frac{\Delta t}{(\Delta x)^2} \Delta_-(a(x_j)\Delta_+ u_j) \\
&+ \frac{\Delta t}{\Delta x} u_j
\end{align*}$$

(4.13)

where

$$\Delta_\pm u_j = \pm (u_{j\pm 1} - u_j)$$

with $\Delta t/(\Delta x)^2 = 0.25$. The number of significant elements in $A^n$ and $(SAS^{-1})^n$ is shown on table 6, and is plotted on figure 8.

For the parabolic problem, the large elements of $A$ are in the neighborhood of the main diagonal. Their wavelet transform image is shown in figure 9. The relative error due to subband truncation was 0.0025.

4.5 Two-dimensional Parabolic Problems. We consider the following problem:

$$\begin{align*}
\partial_t u &= a_{11}\partial_{xx} u + 2a_{12}\partial_{xy} u + a_{22}\partial_{yy} u \\
u(x, y, 0) &= u_0(x, y)
\end{align*}$$
with periodic boundary conditions \((0 \leq x \leq 1, 0 \leq y \leq 1)\). We choose
\[
a_{11}(x, y) = 0.5 + 0.25 \sin(2\pi x)
\]
\[
a_{12}(x, y) = 0.115 \sin(2\pi x) \cos(2\pi y)
\]
\[
a_{22}(x, y) = 0.5 + 0.25 \cos(2\pi y)
\]
\[
u_0(x, y) = \sin(4\pi x) + \cos(8\pi x).
\]

We use a standard two-dimensional explicit central difference scheme. The two-dimensional data \(u_{j,k}, j = 1 \ldots N_1, k = 1 \ldots N_2\) forms a one-dimensional vector in the following way
\[
\{u_{1,1} \ldots u_{1,N_2}, u_{2,1} \ldots u_{2,N_2}, \ldots, u_{N_1,1} \ldots u_{N_1,N_2}\}.
\]

To reduce the size of the problem, \(N_2\) is much less than \(N_1\). In particular we took \(N_1 = 128, N_2 = 8\) that is, \(\Delta x = \frac{1}{128}\) \(\Delta y = \frac{1}{8}\).

The compression worked quite well. Table 7 shows the number of elements in \(A^n\) on \((SAS^{-1})^n\) whose absolute values are greater than \(10^{-4}\). The relative error due to subband truncation was 0.0066.

Acknowledgement

The authors would like to thank V. Rokhlin for suggesting both this problem and this approach to it.

Final Report

We devise a class of fast wavelet based algorithms for linear evolution equations whose coefficients are time independent. The method draws on the work of Beylkin, Coifman, and Rokhlin [1] which they applied to general Calderon-Zygmund type integral operators. We apply a modification of their idea to linear hyperbolic and parabolic equations, with spatially varying coefficients. A significant speedup over standard methods is obtained when applied to hyperbolic equations in one space dimension and parabolic equations in multidimensions.
