Summary

An investigation was conducted in the Langley 14- by 22-Foot Subsonic Tunnel to determine two-dimensional aerodynamic characteristics of nine polygon-shaped models applicable to helicopter fuselages. The models varied from 1/2 to 1/3 scale and were nominally triangular, diamond, and rectangular in cross-sectional shape. Section side-force coefficients \( c_y \) and section normal-force coefficients \( c_z \) were obtained at a dynamic pressure of 20 psf and at incremental angles of flow incidence \( \phi \) from \(-45^\circ\) to \(90^\circ\). The data were compared with results from a study of a UH-60 tail-boom cross-sectional model that served as the baseline configuration. Data from a UH-1 class helicopter were used in calculations to estimate effects of the cross-sectional aerodynamics on tail-rotor power.

The overall shapes of the plots of \( c_z \) and \( c_y \) versus \( \phi \) for the polygon-shaped models were similar to the characteristic shape of the baseline data; however, there were important differences in magnitude. At \( \phi = 0^\circ \), for example, larger maximum values of \( c_z \) for the polygonal models than for the baseline model resulted in a computed increase in fuselage down-load penalties of about 1 to 2.5 percent of main-rotor thrust. Three of the polygonal models had larger values of the slope of \( c_y \) versus \( \phi \) than the baseline configuration had, an indication of potential among the polygonal configurations for producing higher fuselage side-force and yawing moments when the cross sections are incorporated into a helicopter design. Key parameters from the polygon-shaped-model data were compared with UH-60, AH-64, and UH-1 two-dimensional model data previously reported.

Introduction

Single-rotor helicopters are subject to complex airflows generated by the main- and tail-rotor wakes and the ambient wind. These airflows create aerodynamic forces on the fuselage and the tail-boom assembly which, during hover and low-speed sideward flight, must be counteracted by increased main-rotor and tail-rotor thrust to maintain aircraft trim (refs. 1 and 2). The additional thrust increases the power requirements, which results in a reduction in both payload and yaw control margins. The magnitude of the aerodynamic forces on the fuselage is influenced by the cross-sectional shape and size of the fuselage as well as by the angle of attack and dynamic pressure in the wake around the fuselage. To optimize the aerodynamics, a fuselage cross-sectional configuration should be shaped to minimize the down load on the fuselage, which must be offset by additional main-rotor thrust. Also, the side force on the boom should be in the same direction as tail-rotor thrust to help decrease the thrust. The steeper the slope of the fuselage side-force coefficient \( c_y/\phi \) and the larger the positive and negative values of the section side-force coefficient \( c_y \), the more sensitive the fuselage is to the velocity and angle-of-attack changes and the greater the potential is for fuselage yawing moments in crosswinds and sideward flight with the attendant burden on tail-rotor horsepower. The steepness of the slope of \( c_y/\phi \), much like the lift-curve slope for an airfoil, indicates a larger side force for a given angle of flow incidence \( \phi \) as well as increased sensitivity to changes in \( \phi \) or velocity.

Previous studies (refs. 3 to 7) have been made in an effort to understand and modify helicopter tail-boom aerodynamic forces. Both two-dimensional wind-tunnel model and flight investigations were conducted on OH-58, UH-1, AH-64, and UH-60 helicopter tail booms. The two-dimensional tail-boom cross-sectional shapes investigated in the tunnel were generally cylindrical or oval. However, radar detectability requirements of future military helicopters require a change from more traditional designs to low-radar-signature cross-sectional designs that are generally polygon shaped. The aerodynamic characteristics of the polygonal shapes have not been fully investigated, and data from wind-tunnel models are necessary to validate computational methods that will be used to predict aerodynamic effects on vehicle performance and handling qualities.

To provide these data, a wind-tunnel investigation was conducted in the Langley 14- by 22-Foot Subsonic Tunnel with nine two-dimensional polygon-shaped models that varied from 1/2 to 1/3 scale. The models, shown in figure 1, were based on design information from an investigation sponsored by the U.S. Army on fuselage low-radar cross sections and represent possible future fuselage cross sections. The results from the polygon-shaped models were compared with those of a modern U.S. Army utility helicopter tail-boom cross-sectional model (UH-60), which served as the baseline configuration (ref. 3). When calculations were made to determine the effect of side-force characteristics on tail-rotor power, a UH-1 class helicopter (Bell 204B) was used because of the type of flight data available. Aerodynamic forces were measured at a free-stream dynamic pressure \( q_c \) of 20 psf for angles of \( \phi \) from \(-45^\circ\) to \(90^\circ\). The baseline configuration data were taken at \( q_c = 25 \text{ psf} \) (ref. 3). The results are presented as the section normal-force coefficient \( c_z \) and \( c_y \) as a function of \( \phi \) for each configuration and are compared with results from the baseline model tests. Calculations based on an assumed helicopter were made to obtain the
approximate effects of the variations in side-load and down-load section coefficients on tail-rotor and main-rotor power required compared with those of the baseline configurations.

Symbols

Conventions for positive sense of flow inclination, model reference dimensions, and aerodynamic coefficients are shown in figure 2.

- \( b \): maximum width of model, in.
- \( c \): maximum depth of model, in.
- \( c_y \): section side-force coefficient. Side force per unit length
- \( c_z \): section normal-force coefficient. Longitudinal force per unit length
- \( b q_{\infty} \): power-factor ratio of tail-rotor power required to balance aerodynamic force of tail boom with polygonal cross sections to tail-rotor power required to balance aerodynamic force of baseline (Bell 204B) tail boom
- \( q_{\infty} \): free-stream dynamic pressure, \( \frac{1}{2} \rho V^2 \), psf
- \( R \): Reynolds number, \( \frac{\rho V c}{\mu} \)
- \( r \): corner radii of fuselage cross section, in.
- \( \frac{\Delta T_{\text{mo}}}{T_{\text{mo}}} \): change in main-rotor thrust required for helicopter with tail boom equipped with the polygon-shaped cross sections compared with helicopter with baseline (UH-60) tail boom
- \( V_{\infty} \): free-stream velocity in tunnel, ft/sec
- \( \beta \): angle of sideslip, positive with relative wind approaching aircraft from the right, deg
- \( \mu \): absolute viscosity, slug/ft-sec
- \( \rho \): free-stream air density, slug/ft^3
- \( \phi \): angle of flow incidence in plane normal to axis of two-dimensional cylinder, deg

Abbreviations:

- BL: baseline
- TRDSC: tail-rotor drive-shaft cover

Model and Apparatus

Nine polygon-shaped models representative of cross sections of rotorcraft fuselages or tail booms were tested. The models varied from approximately \( \frac{1}{2} \) to \( \frac{1}{3} \) scale. Dimensions and cross-sectional shapes of the nine models and of the baseline UH-60 tail-boom model are shown in figure 1. Model configurations \( S_1 \) and \( S_2 \) were both basically triangular, with rounded corners on the bottom. Configuration \( S_1 \) had a flat top and configuration \( S_2 \) had a rounded top that could serve as a tail-rotor drive-shaft cover (TRDSC). Configurations \( S_3 \) and \( S_4 \) were both diamond shaped, with a nearly flat bottom. Configuration \( S_4 \) had a pointed top and configuration \( S_3 \) had a small, flat top. Configurations \( S_5 \) and \( S_6 \) were truncated triangles. Configuration \( S_6 \) had a TRDSC shape on top of the truncation. Configurations \( S_7 \) and \( S_8 \) had a diamond shape on top of the truncation except for larger flat tops. Configuration \( S_8 \) had a TRDSC shape on top. Configuration \( S_9 \) was basically a vertical rectangle with rounded corners and had a TRDSC shape on top. The baseline model section was taken from the tail boom of a UH-60 at a station approximately under the 80-percent-radius station of the main-rotor blade and was a rounded oval shape with a TRDSC on top.

The models were constructed of aluminum sheet metal attached to aluminum bulkheads with flush mounting screws. The surfaces were smooth without the protruding rivet heads characteristic of helicopter fuselages and tail booms. Configurations \( S_4 \), \( S_5 \), \( S_7 \), and \( S_8 \) were fabricated from wood and aluminum. The model reference dimensions and directions of aerodynamic coefficients are shown in figure 2.
distributed two-dimensional flow would occur on the metric section.

Test Procedures and Accuracy

Data were taken at a constant \( q_\infty \) as the model was rotated through the range of \( \phi \) from \(-45^\circ\) to \(90^\circ\). Data were taken every 5° from \(-25^\circ\) to \(30^\circ\) and every 10° from \(-45^\circ\) to \(-25^\circ\) and from \(30^\circ\) to \(90^\circ\). These angles are equivalent to an angle of attack on the helicopter fuselage or tail boom due to main-rotor downwash and sideward flight airspeeds. The value \( q_\infty = 20 \text{ psf} \) was selected to include the approximate Reynolds numbers experienced by full-scale helicopters \((1.0 \times 10^6 < R < 1.8 \times 10^6)\). Free-stream dynamic pressure, as it relates to Reynolds number, is shown in figure 5 for the baseline model and the nine polygonal models.

During calibration with all beams fully loaded, the strain-gage balance used in the test apparatus for each of the models had an accuracy for both normal force and side force of ±1.25 lb; however, the general repeatability of the force measurements was found to be approximately ±0.20 lb. The balance had an accuracy at \( q_\infty = 20 \text{ psf} \) of ±0.003 for both normal-force coefficient and side-force coefficient, with a repeatability determined to be ±0.001 for the coefficients.

Because the maximum test free-stream Mach number was 0.11, compressibility effects were negligible. Because of the small volume of the apparatus relative to the test-section volume, the data did not require correction for blockage effects (ref. 9).

Based on results in reference 3, several factors were considered that could have caused uncertainties in the data, such as model surface roughness, \( R \), hysteresis effects caused by flow separation, and flow turbulence level in the test section. For the first factor, the model surface was not polished, but unlike typical helicopter fuselage surfaces it had no rows of rivet heads. The sheet metal was secured on the model frame by sunken screws. The screw holes were then taped over.

Regarding the second factor, lift and drag forces measured on the models are known to vary widely as a function of tunnel velocity, particularly in the critical \( R \) range. Full-scale rotorcraft experience varying values of \( R \), and for \( R = 0.3 \times 10^6 \) to \(0.7 \times 10^6\), large changes are known to occur in lift and drag on blunt bodies such as these. Because the data in this investigation were taken at \( R = 1.0 \times 10^6 \) to \(1.8 \times 10^6 \) (fig. 5), large changes in aerodynamic forces as a function of \( R \) were not a concern (refs. 10 and 11).

A third factor that can affect aerodynamic results as a function of angle of attack or airspeed is hysteresis caused by flow separation. This effect can influence the sequence used when \( q_\infty \) or \( \phi \) are varied to take data points. To determine the effects of changing the sequence of \( \phi \) at a given \( q_\infty \), several runs were made for \( \phi = -45^\circ \) to \(90^\circ\) and then for \( \phi = 90^\circ \) to \(-45^\circ\). The results indicated that there was relatively little difference in the data. Hysteresis in the data can also be experienced during a \( q_\infty \) sweep. If, for example, one run is taken with \( q_\infty \) increasing and the next taken with \( q_\infty \) decreasing, repeatability of the data may be poor. This effect was avoided by increasing tunnel \( q_\infty \) from 0 to 20 psf and then varying \( \phi \) in increments consistently from \(-45^\circ\) to \(90^\circ\).

The final factor considered was turbulence in the tunnel test section. Because of recent improvements to the 14- by 22-Foot Subsonic Tunnel, the turbulence level was only 0.1 percent of free-stream velocity (ref. 8).

Presentation of Data

The results are presented as the section normal-force coefficient \( c_n \) and the section side-force coefficient \( c_s \) as a function of angle of flow incidence \( \phi \). Summary charts for the parameters \( c_n/\phi \) and \( c_s \) at \( \phi = 0^\circ \) for configurations \( S_1 \) to \( S_9 \) and calculated effects of these parameters on tail-rotor and main-rotor power are also presented. The coefficients are based on the dimension \( b \) (maximum width of model), which is consistent with presentation of data in reference 3 and references 10 to 15. The baseline tail-boom cross-sectional data were obtained from reference 3.

The data are presented as follows:

Aerodynamic characteristics of configuration S9 and baseline. Slope $c_y/\phi$ for configurations S1 to S9 and baseline. Tail-rotor power factor calculated from $c_y$ for configurations S1 to S9 and UH-1. Value of $c_z$ at $\phi = 0^\circ$ for configurations S1 to S9 and baseline. Calculated effect of $c_z$ at $\phi = 0^\circ$ on main-rotor thrust ($\Delta T_{\text{mr}}/T_{\text{mr}}$) for configurations S1 to S9 and baseline.

Discussion of Results for General Aerodynamic Characteristics

The section side-force coefficient $c_y$ and section normal-force coefficient $c_z$ as a function of $\phi$ are presented and discussed. The data from the polygon-shaped sections are compared with data from the UH-60 baseline as well as with data from the other polygon models. Results from calculations based on these data are presented to show the effects of $c_z$ and $c_y$ on main-rotor and tail-rotor power relative to that of the baseline.

The relationship between $\phi$ and the sideward velocity of a helicopter in combination with downwash velocity from the main rotor can be expressed with simplifying assumptions as $\tan \phi = \text{Sideward velocity}/\text{Average downwash velocity}$. If a UH-1-sized helicopter weighing 8000 lb with a rotor 48 ft in diameter is assumed, the rotor disk loading is calculated to be about 4.4 lb/ft$^2$ in hover. A rule-of-thumb assumption is that, in hover, the average downwash dynamic pressure is equal to disk loading; therefore, the average downwash velocity is computed to be about 60 ft/sec. In left or right sideward flight then, $\tan \phi = \text{Sideward velocity}/60 \text{ ft/sec}$, and a sideward velocity of 35 knots yields an angle of flow incidence $\phi$ at the fuselage of 45°. The sideward-flight-speed envelope for many helicopters is 0 to 35 knots; therefore, if a large percentage of the operational time is spent to be between 20 knots right and 20 knots left, then the speed range could be represented by an equivalent range of $\phi$ of -30° to 30°.

Configurations S1 to S9 Versus Baseline

A summary of $c_z$ and $c_y$ as a function of $\phi$ for configurations S1 to S9 and for the baseline is presented in figure 6. The results indicate a wide variation in $c_z$ and $c_y$ over the range of $\phi$ investigated. The variations were not unexpected, based on the diversity of blunt shapes under consideration. The larger the positive value of $c_z$, the higher the fuselage down-load penalty that must be compensated for by main-rotor thrust. Within $-15^\circ < \phi < 15^\circ$, $c_z$ is higher for S1 to S9 than for the baseline. For comparison purposes, at $\phi = 0^\circ$ a majority of the configurations (S1 to S8) result in values of $c_z$ that are from 3.0 to 3.5 times larger than the baseline values. For S9, $c_z$ at $\phi = 0^\circ$ is about twice as large as $c_z$ at $\phi = 0^\circ$ for the baseline.

Results of the data for $c_y$ versus $\phi$ (fig. 6(b)) indicate a group of three configurations (S1, S2, and S9) that have slopes ($c_y/\phi$) which are steeper than the slope of the baseline data within the linear range $-10^\circ < \phi < 10^\circ$. Also for these configurations, the larger positive and negative values of $c_y$ are about 2 times as large as the larger baseline values. The remaining configurations (S3 to S8) for $-10^\circ < \phi < 10^\circ$ have values of $c_y/\phi$ that vary from about one-third to one-eighth of the baseline value. Configuration S4, which is a flat-bottom diamond with a blunt top, has a slope of $c_y/\phi$ of about one-seventh of the baseline value within $-10^\circ < \phi < 10^\circ$. More detailed comparisons of configurations S1 to S9 are presented in figures 7 to 13.

Configurations S1, S3, S5, and S7 Versus Baseline

Cross-sectional configurations S1, S3, S5, and S7 (polygon shapes without a representative TRDSC) are compared with the baseline configuration in terms of $c_z$ and $c_y$ as a function of $\phi$ in figure 7. The configurations are representative of fuselage cross sections forward of a tail boom because no TRDSC is included in the shape.

Configurations S1, S3, S5, and S7 all have higher values of $c_z$ for $-15^\circ < \phi < 25^\circ$ compared with the baseline values. This result is not unexpected because the baseline configuration has a smooth oval shape compared with the triangular- and diamond-shaped configurations without a TRDSC contour on top. Configuration S3 has the highest value of $c_z$ for $-30^\circ < \phi < 25^\circ$, with the $c_z$ values of S1, S5, and S7 being grouped together at $-10^\circ < \phi < 10^\circ$ but noticeably less (about 25 percent) at $\phi = 0^\circ$ when compared with S3. It is not obvious by visual inspection of the shapes of S1, S3, S5, and S7 why the values of $c_z$ fall in this order.

At the more extreme values of $\phi$ investigated ($-45^\circ < \phi < -20^\circ$ and $25^\circ < \phi < 90^\circ$), values of $c_z$ for the baseline configuration are within the range of the values of $c_z$ for all the polygon-shaped configurations. Because the magnitude of fuselage down load is important in hover and low-speed flight (fuselage down-load loss varies between about 3 and 8 percent of total main-rotor thrust, depending on the particular helicopter design), the magnitude of $c_z$—
which depends on fuselage size and shape—must be
given serious consideration by the designer. If a large
percent of the low-speed operational time is assumed
to be in the range of $-30^\circ < \phi < 30^\circ$ (between
about 20 knots right and 20 knots left), the down-
load penalty on a helicopter that uses S1, S3, S5, and
S7 in the tail boom and fuselage would be expected to be
appreciably higher compared with the penalty on one
that uses fuselage sections shaped like the baseline
configuration. In fact, if just the tail-boom portion
of the fuselage is considered, and if it is assumed
that the tail boom is responsible for one-fourth of
the down-load penalty of a given helicopter fuselage
that has a total fuselage down load of 4 percent of
main-rotor thrust, then a tripling of the value of the
baseline c2 at $\phi = 0^\circ$ would result in a revised total
fuselage down load of 6 percent, or a loss in overall
vehicle lift capability of about 2 percent. Likewise,
if the c2 were doubled compared with that of the
baseline configuration, the loss in lift would be an
additional 1 percent, for a total of 5 percent.

The linear portions of the curves of cy versus $\phi$
in figure 7(b) are contained for the most part at
$-10^\circ < \phi < 10^\circ$ and reflect attached flow (i.e., small
degree of flow separation) on the models. The data
at $\phi > 10^\circ$ and $\phi < -10^\circ$ represent conditions of
massive flow separation (i.e., stall). At $-10^\circ < \phi$
$< 10^\circ$, the steeper the slope of $c_y/\phi$, the higher the
potential side-force sensitivity for a given helicopter
fuselage that incorporates these shapes in its design.
Because these nine shapes are generally applicable
to fuselage sections (both tail boom and sections
forward of the tail boom), the effect of the steepness
of $c_y/\phi$ on the net fuselage yawing moment would be
an integrated effect along the entire fuselage length.
Also, high fuselage side forces would result from large
positive and negative values of $c_y$, and correcting for
these forces requires some angle of bank to trim the
vehicle when hovering over a spot on the ground in
a crosswind.

The baseline configuration has a large value of
$c_y/\phi$ when compared with those of other typical heli-
copter tail-boom cross-sectional configurations such
as the UH-1 and the AH-64 (table I). Interestingly,
S1 (narrow truncated triangle shape) has a slope that
is approximately 30 percent steeper than that of the
baseline configuration for $-10^\circ < \phi < 10^\circ$, and the
maximum positive and negative values for $S1$ of $c_y$
at $\phi = -20^\circ$ and $\phi = 15^\circ$, respectively, are about
2 times as large as the largest values of $c_y$ for the
baseline configuration. Also, $c_y$ remains high for
$15^\circ < \phi < 90^\circ$ and $-45^\circ < \phi < -20^\circ$ for $S1$. The
values of $c_y/\phi$ at $-10^\circ < \phi < 10^\circ$ for configurations
S3, S5, and S7 are about 13 percent, 38 percent, and
24 percent of the baseline $c_y/\phi$, respectively. The
value of the shallow slope of $c_y/\phi$ that is characteris-
tic of the $S3$ configuration (flat-bottom diamond with
a blunt top) is similar to the value obtained on a two-
dimensional circular cylinder reported in reference 3
table I).

Configurations $S2$, $S4$, $S6$, $S8$, and $S9$
Versus Baseline

Results from the polygon-shaped fuselage config-
urations equipped with representative TRDSC's ($S2$,
$S4$, $S6$, $S8$, and $S9$) are shown with those from the
baseline configuration in figure 8. These configura-
tions are geometrically similar to those considered in
figure 7 except for the addition of the S9 configura-
tion (narrow rectangular shape with representative
TRDSC). The variations of $c_z$ and $c_y$ with $\phi$ (fig. 8)
are similar to the results shown in figure 7 and dis-
cussed in the previous section, with the addition of
TRDSC's having a small effect on the overall results.
The S9 configuration produces $c_z$ and $c_y$ results that
are expected based on results from S2, which has a
somewhat similar shape.

Figure 8(a) shows that the maximum $c_z$ value at
$\phi = 0^\circ$ results from S1. Also, the maximum value of
$c_z$ for S4 is approximately the same as that for S3 in
figure 7(a). Within $-10^\circ < \phi < 10^\circ$, the value of $c_z$
for the remaining configurations with TRDSC's fall
above the baseline values.

The results shown in figure 8(b) are similar to
those in figure 7(b), except that the addition of S9 to
the group results in values of $c_y/\phi$ and maximum po-
sitive and negative values of $c_y$ on the order of those
for S1 and S2. The comments given in the previous
section regarding the results shown in figure 7(b) also
generally apply to the results in figure 8(b).

Configurations With and Without a
TRDSC

In this section of the paper, the effects on $c_z$
and $c_y$ of similarly shaped configurations with and
without a TRDSC ($S1$ and $S2$, $S3$ and $S4$, $S5$ and
$S6$, and $S7$ and $S8$) are discussed and compared
with the effects of the baseline configuration. The
results are presented in figures 9 to 12. The results
for configuration S9 alone are compared with the
baseline in figure 13. Key values ($c_z$, at $\phi = 0^\circ$ and
$c_y/\phi$ at $-10^\circ < \phi < 10^\circ$) taken from the data for
configurations S1 to S9 are presented in table II. The
same values for large-scale UH-60, UH-1, and AH-64
models taken from reference 3 are given in table I
to provide additional comparisons. Data for these
models were obtained in the same range of Reynolds
numbers as that for S₁ to S₉. The tail-boom sections (UH-1, UH-60, and AH-64) were modeled from a boom station under the 80-percent main-rotor-blade radial station.

**S₁ versus S₂ versus baseline.** The results for the narrow triangular configurations, one with a truncated top (S₁) and the second with a rounded top that modeled a TRDSC (S₂), are presented with the baseline results in figure 9. The results show a much larger c₂ for S₁ and S₂ compared with that of the baseline for $-15^\circ < \phi < 10^\circ$ (fig. 9(a)). At $\phi = 0^\circ$, c₂ for S₁ and S₂ is about 3 times larger than the baseline c₂. Also, at $25^\circ < \phi < 90^\circ$, the values of c₂ for S₁ and S₂ are lower than those for the baseline. The TRDSC on S₂ appears to have little effect in reducing c₂ compared with S₁. The S₁ and S₂ shapes with higher values of c₂ will yield larger down-load losses than will the baseline when incorporated into a helicopter fuselage.

Measurements in the linear portion of the curves in figure 9(b) ($-10^\circ < \phi < 10^\circ$) indicate that S₁ and S₂ have about 30 percent and 40 percent steeper slopes, respectively, than the baseline. The steepness of the slopes within this range of φ and the generally high values of c₂ throughout the rest of the φ range indicate that, if these shapes were incorporated into a helicopter fuselage design, higher side-force and yawing-moment characteristics would likely result for S₁ and S₂ compared with the baseline. The effect of the TRDSC on S₂ compared with S₁ results in a steeper slope in the linear range and larger positive and negative values of c₂ for φ beyond the linear range ($15^\circ < \phi < -20^\circ$).

**S₃ versus S₄ versus baseline.** Results for the S₃, S₄, and baseline configurations are presented in figure 10. The values of c₂ at $-20^\circ < \phi < 20^\circ$ for S₃ and S₄ are much larger than the values for the baseline, and at $\phi = 0^\circ$, the values for S₃ and S₄ are about 3.5 times larger than the baseline value (fig. 10(a)). In figure 10(b), slopes of c₂/φ within $-10^\circ < \phi < 10^\circ$ for S₃ and S₄ are low compared with c₂/φ of the baseline. The slope of c₂/φ for S₃ is the lowest of the nine polygon-shaped configurations investigated and, in fact, is nearly as low as c₂/φ for a circular cylinder reported in reference 3. (See tables I and II.) Within the same range of φ ($-10^\circ < \phi < 10^\circ$), S₄ has a value of c₂/φ about the same as that obtained on the two-dimensional AH-64 tail-boom model (cylindrical shape with a TRDSC) investigated in reference 3. (See tables I and II.) The TRDSC (pointed top) results in a steeper slope of c₂/φ for S₄ than for S₃ in the linear part of the curves. It has a negligible effect on c₂ at $\phi = 0^\circ$ and reduces c₂ at $-35^\circ < \phi < -10^\circ$ and $15^\circ < \phi < 35^\circ$.

Outside the linear range of data points for $-10^\circ < \phi < 10^\circ$, the absolute values of c₂ for S₃ and S₄ are generally lower than those for the baseline. If incorporated into a helicopter fuselage design, S₃ and S₄ would likely result in low fuselage side-force and yawing-moment characteristics compared with those of the UH-60 baseline model.

**S₅ versus S₆ versus baseline.** The results for the S₅, S₆, and baseline configurations are shown in figure 11. The figure shows results similar to those of the other configurations investigated, with values of c₂ for S₅ and S₆ at $-15^\circ < \phi < 15^\circ$ being much greater than those for the baseline. For $-15^\circ < \phi < 15^\circ$, the values of c₂ for S₅ and S₆ are virtually identical. At $\phi = 0^\circ$, c₂ is about 2.7 times larger than the baseline value (0.8 versus 0.3). The TRDSC on S₅ appears to be effective in reducing c₂ compared with those of S₅ and the baseline for $-45^\circ < \phi < -25^\circ$ and $25^\circ < \phi < 55^\circ$.

Compared with the baseline configuration (fig. 11(b)), configurations S₅ and S₆ have a lower c₂/φ for $-10^\circ < \phi < 10^\circ$. (See table II for values.) The magnitudes of c₂/φ for configurations S₅ and S₆ are virtually identical for $-20^\circ < \phi < 15^\circ$, which indicates that the TRDSC on configuration S₆ has little or no aerodynamic effect in this range of φ. Compared with the baseline values, the values of c₂/φ for S₅ and S₆ in the linear range of φ are low (about 2.7 times lower than the baseline). Based on comparison with data in tables I and II, if these configurations were used in a helicopter fuselage design, the fuselage side-force and yawing-moment characteristics would be expected to be low compared with those of the tail-boom cross-sectional configurations on the UH-60 and UH-1 helicopters. The values of c₂/φ for S₅ and S₆ are, however, larger in magnitude than the values of c₂/φ for the AH-64.

**S₇ versus S₈ versus baseline.** The results for the S₇, S₈, and baseline configurations are presented in figure 12. Both S₇ and S₈ have a much larger c₂ within $-20^\circ < \phi < 20^\circ$ than that of the baseline. At $\phi = 0^\circ$, c₂ for S₇ and S₈ are 2.5 to 3 times that of the baseline. (See table II.) The effect of the TRDSC on the results of S₈ at $-45^\circ < \phi < -25^\circ$ and $25^\circ < \phi < 60^\circ$ is of interest because c₂ for S₈ is much lower than it is for S₇ and for the baseline. For $70^\circ < \phi < 90^\circ$, S₇ (without a TRDSC) has the lowest c₂ and the baseline has the largest value. Because much of the operational time for a helicopter is at $-30^\circ < \phi < 30^\circ$ (equal to sideward flight speeds of about 0 to 20 knots), where c₂ for configurations
$S_7$ and $S_8$ is 2.5 to 3 times that of the baseline configuration, the down-load penalty for $S_7$ and $S_8$ fuselage designs will be much greater than that of the baseline.

In the range of $\phi$ where the data are linear in figure 12(b) ($-10^\circ < \phi < 10^\circ$), configurations $S_7$ and $S_8$ have identical slopes (see values in table II), and this equality indicates that the TRDSC has no effect on $c_z$ in this range of $\phi$. The side-force and yawing-moment characteristics of $S_7$ and $S_8$ when included in a fuselage design will likely be low compared with those generated by the baseline and are on the same order as those of a circular tail boom with a TRDSC (AH-64). (See tables I and II.)

$S_9$ versus baseline. The results for configuration $S_9$ (narrow rectangular shape with a TRDSC) and the baseline results are given in figure 13. The $c_z$ (fig. 13(a)) is higher for $S_9$ at $-10^\circ < \phi < 10^\circ$ and is about 2 times larger than that of the baseline at $\phi = 0^\circ$. For $45^\circ < \phi < 90^\circ$, $c_z$ for $S_9$ is about one-third the baseline value.

The value of $c_y/\phi$ for $S_9$ (fig. 13(b)) is about 60 percent greater than for the baseline at $-10^\circ < \phi < 10^\circ$. In fact, of the nine configurations investigated, $S_9$ results in the steepest slope. It should also be noted that the largest positive and negative values of $c_y$ for $S_9$ are about twice as large as the corresponding values of $c_y$ for the baseline configuration, and the margin continues throughout $-15^\circ > \phi > 15^\circ$. $S_9$ would be expected to have high side-force and yawing-moment characteristics compared with those of the baseline when incorporated in a helicopter fuselage design.

Effect of Side-Force Characteristics ($c_y/\phi$ and maximum $c_y$) on Tail-Rotor Power

Figure 14 presents a bar chart of $c_y/\phi$ for $-10^\circ < \phi < 10^\circ$ for configurations $S_1$ to $S_9$ and the baseline. The effects of the maximum value of $c_y$ on tail-rotor power were then calculated for configurations $S_1$ to $S_9$ based on a UH-1 class (Bell 204B) helicopter and are presented with flight data from the 204B (ref. 6) in figure 15. The 204B helicopter was used as a baseline configuration in this case because of the type of flight data available.

The data represented in the summary bar chart (fig. 14) are taken from the linear portion of the slopes between $-10^\circ < \phi < 10^\circ$. Configurations $S_1$, $S_2$, and $S_8$ have slopes that are greater than that of the baseline and therefore, in crosswinds could be expected to yield higher side-force characteristics than the baseline configuration when used in a helicopter fuselage. Also, higher values of $c_y/\phi$ contribute to higher fuselage yawing moments, which in right crosswinds (positive $\phi$) would increase the tail-rotor power required. In right crosswinds, the tail rotor normally thrusts to the right; therefore, a positive value of $c_y$ will then assist in yaw control.

Calculations based on a right crosswind condition of an airspeed of 20 knots and wind coming from $60^\circ$ to the right of the nose of a UH-1 class (Bell 204B) helicopter indicate that the tail-rotor power required to overcome the boom force when configurations $S_1$ to $S_9$ are used in the tail boom would vary from about 0.3 to 2.3 times the power required of the baseline Bell 204B (fig. 15). Data are available from both flight investigation (ref. 6) and wind-tunnel investigation (ref. 3) to use in the calculations. The calculations are based on the following rationale. If the maximum value of $c_y$ for configuration $S_9$ ($-3.0$ at $\phi = 15^\circ$, fig. 13(b)) is compared with the corresponding value for the UH-1 tail-boom model ($-1.3$ with TRDSC, ref. 3), an estimate of the tail-rotor power needed to overcome the boom force can be made. The size and shape of the UH-1 and 204B tail booms are identical. The maximum measured $c_y$ for the UH-1 model is assumed to represent the maximum boom contribution to tail-rotor power required (20 hp for full-scale helicopter for these conditions, ref. 6). When the maximum $c_y$ for configuration $S_9$ is divided by the maximum value of $c_y$ for the UH-1, the result is $3.0/1.3 = 2.3$; therefore, the maximum tail-boom contribution to tail-rotor power required for configuration $S_9$ is approximately $2.3 \times 20$ hp = 46 hp if configuration $S_9$ is installed as the boom shape on a UH-1 class helicopter. In terms of overall power, if the helicopter is assumed to require 600 hp to hover in a 20-knot wind, the change in tail-rotor power of 26 hp (46 hp - 20 hp = 26 hp) for the helicopter with an $S_9$ configured boom compared with the baseline represents an increase of 4.3 percent. It must be remembered for these calculations that two-dimensional data are being applied with three-dimensional data, so the results shown in figure 15 indicate trends only.

Effect of Down-Load Characteristics ($c_z$ at $\phi = 0^\circ$) on Main-Rotor Power

A summary bar chart that presents the section normal-force (down-load) coefficients $c_z$ at $\phi = 0^\circ$ for configurations $S_1$ to $S_9$ with those for the baseline configuration is given in figure 16. The down loads of all the polygon-shaped configurations are much higher than that of the oval-shaped baseline model because of the flat surfaces normal to the flow and
the increased surface area. With the same assumptions as given previously, the effects on main-rotor thrust of tail-boom down load in hover are computed and the results are presented in figure 17. If the polygon-shaped models are substituted for the baseline UH-60 tail boom, the calculated increase in hover down load on the boom would require an additional main-rotor thrust of approximately 1 to 2.5 percent. Again, the assumptions included in the calculations make the accuracy of the derived values questionable; however, the trends are believed to be applicable.

**Concluding Remarks**

An investigation was conducted in the Langley 14- by 22-Foot Subsonic Tunnel to determine the aerodynamic characteristics of nine large-scale two-dimensional polygon-shaped fuselage models that were nominally triangular (configurations S1, S2, S5, and S6), diamond (configurations S3, S4, S7, and S8), and rectangular (configuration S9) in shape. Section side-force coefficients $c_y$ and normal-force coefficients $c_n$ were obtained on each model at angles of incidence $\phi$ from $-45^\circ$ to $90^\circ$ and compared with results from a UH-60 tail-boom cross-sectional model that served as the baseline configuration. Two-dimensional data from AH-64 and UH-1 tail-boom models were also used for comparison. Calculations were performed to obtain an approximation of effects of side-load and down-load characteristics of the polygon-shaped models on main- and tail-rotor thrust and power compared with those of a baseline. Based on analyses of results from this investigation, the following observations can be made:

1. The general trends of $c_2$ and $c_y$ as a function of $\phi$ for the nine polygon-shaped models were similar to the characteristic trend of the UH-60 baseline model data; however, there were important differences in magnitude.

2. Within $-15^\circ < \phi < 15^\circ$, values of $c_2$ for S1 to S9 were larger than that for the UH-60 baseline model. At $\phi = 0^\circ$, values of $c_2$ for S3 and S4 were the largest of the nine configurations at about 3.5 times the baseline value. Configuration S9 had the lowest value at about 2 times the baseline value.

3. The calculated increase in fuselage down load for the nine polygon-shaped configurations varied from 1.0 to 2.5 percent of main-rotor thrust compared with the UH-60 baseline.

4. Configurations S1, S2, and S9 yielded greater slopes of $c_y/\phi$ at $-10^\circ < \phi < 10^\circ$ than the UH-60 baseline. Steeper slopes of $c_y/\phi$ and higher positive and negative values of $c_y$ result in fuselage designs that are likely to produce higher side-force and yawing-moment characteristics than the baseline.

5. Configurations S3 to S8 had lower slopes of $c_y/\phi$ compared with the baseline within $-10^\circ < \phi < 10^\circ$. The values were closer to the value of a circular cylinder with a tail-rotor drive-shaft cover. Compared with the baseline, configurations S3 to S8 will result in moderate to low side-force and yawing-moment characteristics when incorporated into a helicopter fuselage design.

6. Calculations based on the maximum value of $c_y$ for S1 to S9 indicate that the tail-rotor power required to overcome the tail-boom side force varied from about 0.3 to 2.3 times the baseline (Bell 204B helicopter) value.

### Two-Dimensional Aerodynamic Characteristics of Several Polygon-Shaped Cross-Sectional Models Applicable to Helicopter Fuselages

Henry L. Kelley, Cynthia A. Crowell, and John C. Wilson

#### Abstract

A wind-tunnel investigation was conducted to determine two-dimensional aerodynamic characteristics of nine polygon-shaped models applicable to helicopter fuselages. The models varied from \( \frac{1}{2} \) to \( \frac{5}{8} \) scale and were nominally triangular, diamond, and rectangular in shape. Side force and normal force were obtained at increments of angle of flow incidence from \(-45^\circ\) to \(90^\circ\). The data were compared with results from a baseline UH-60 tail-boom cross-sectional model. The results indicate that the overall shapes of the plots of normal force and side force were similar to the characteristic shape of the baseline data; however, there were important differences in magnitude. At a flow incidence of \(0^\circ\), larger values of normal force for the polygon models indicate an increase in fuselage down load of 1 to 2.5 percent of main-rotor thrust compared with the baseline value. Also, potential was indicated among some of the configurations to produce high fuselage side forces and yawing moments compared with the baseline model.
