ABSTRACT

An Intelligent Control System for reusable rocket engines is under development at NASA Lewis Research Center. The primary objective is to extend the useful life of a reusable rocket propulsion system while minimizing between flight maintenance and maximizing engine life and performance through improved control and monitoring algorithms and additional sensing and actuation. This paper describes current progress towards proof-of-concept of an Intelligent Control System for the Space Shuttle Main Engine. A subset of identifiable and accommodatable engine failure modes is selected for preliminary demonstration. Failure modes are developed retaining only first order effects and included in a simplified nonlinear simulation of the rocket engine for analysis under closed loop control. The engine level coordinator acts as an interface between the diagnostic and control systems, and translates thrust and mixture ratio commands dictated by mission requirements, and engine status (health) into engine operational strategies carried out by a multivariable control. Control reconfiguration achieves fault tolerance if the nominal (healthy engine) control cannot. Each of the aforementioned functionalities is discussed in the context of an example to illustrate the operation of the system in the context of a representative failure. A graphical user interface allows the researcher to monitor the Intelligent Control System and engine performance under various failure modes selected for demonstration.

INTRODUCTION

Reusable rocket engines present a very challenging operational environment and require high performance, low maintenance, and man-rated reliability levels. Multiple start-stop cycles cause thermal gradients with high thermal strains per cycle within the engine. High steady state operating stresses create large inelastic strains. High dynamic loads induce high cycle stresses. In the Space Shuttle Main Engine (SSME), an operational version of a reusable rocket engine, high performance and reliable operation have been achieved. However, originally predicted levels of usable life have not been demonstrated and extensive between flight maintenance has resulted.

Merrill and Lorenzo have proposed a framework outlining specific functionalities to improve the durability of the SSME which include active control of key engine parameters, real time diagnostics, and life extending control. A functional framework showing the various capabilities included in the Intelligent Control System (ICS) is given in Figure 1. The principal components include a distributed diagnostic system, an intelligent coordinator, and a reconfigurable controller. The distributed diagnostic system is composed of sensor validation, a model based failure detector, a rule based failure detector, ReREDS (reusable rocket engine diagnostic system) and a diagnostic expert system. ReREDS is a condition monitoring/diagnostic software system developed during the past two years through a contract with System Control Technology (SCT) and Aerojet. The engine level coordinator in Figure 1 makes alterations to the controller using engine status information generated by the diagnostic system, and propulsion requirements passed down by the propulsion level coordinator as the controller. Each SSME is part of the propulsion system for the orbiter vehicle and is orchestrated by the propulsion level controller which receives thrust vector commands from the flight controller to achieve mission success. Ultimately, the engine level controller must satisfy minimum thrust requirements while minimizing further component degradation and accommodating failed or degraded engine hardware. The reconfigurable controller takes requests generated by the coordinator, makes the changes gradually thereby minimizing engine transients, and computes the valve positions to achieve the requested behavior from the engine.
This paper describes an ongoing research program at the NASA Lewis Research Center to demonstrate an ICS for a reusable space propulsion system (SSME). A significant milestone for the ICS program is the successful integration of real time diagnostics with a reconfigurable control system providing motivation for demonstration with a subset of accommodable failure modes. The focus of this work is on failure mode modelling, controls and coordination, and the graphical user interface. Detailed discussion of the distributed diagnostic system appears elsewhere. An accommodation strategy for a particular failure mode is discussed in detail and simulation results are presented to clarify the various functionalities and potential benefits of the Intelligent Control System.

FAILURE MODES

Modelling failure modes for the ICS project presents a difficult challenge due to several competing objectives. On the one hand there is the desire to accurately describe the progress and effects of a given failure as it occurs. Typically, this requires models not only for the relevant fluid dynamics but for the structural dynamics as well. Such models are necessarily computationally intensive and time consuming to develop. On the other hand, there is the desire to maintain simple models such that real time simulation may be achieved with existing computer hardware. The real time requirement is necessitated by the fact that the diagnostic system and controller under development will eventually be placed on an actual engine, and must therefore respond within the appropriate time scale. Simple failure models also require much less time to develop and are readily available for use in detection and accommodation studies for development of an expert system rule base.

At this point in time, the focus of the project is proof of concept. Therefore, a philosophy of maximum simplicity has been adopted for the task of modelling rocket engine failures. By this we mean that the consequences of a given failure are sought without regard to the cause or the relative time that the failure takes to develop. The following discussion details models for several failure modes selected for demonstration of an ICS. Motivation for their selection will be presented, along with a description of their implementation in the real time simulation model of the SSME. In addition, open loop transient of key engine parameters are provided to illustrate the qualitative behavior of the models.

FAILURE MODE SELECTION

The following five failure modes have been selected for the preliminary ICS demonstration: a failure of a control sensor (Pc), a frozen Fuel Preburner Oxidizer Valve (FPOV), a Low Pressure Fuel Turbo Pump (LPFTP) shaft seal system failure, a High Pressure Fuel Turbo Pump (HPFTP) turbine tip seal failure, and a High Pressure Oxidizer Turbo Pump (HPOTP) shaft seal system failure. One of the primary goals of the project is to examine a variety of techniques for failure detection and accommodation since no one is expected to perform well for all types of failures. The modes listed above cover a broad class of possible problems for the engine with the exception of bearing failures. Unfortunately, the real time engine simulation used for this work does not readily lend itself to including failure modes involving vibration, or other structural phenomena.

Sensor failures and actuator failures are among the most straightforward to implement and require no modelling. Consequently, they have been omitted from the following discussion. The HPOTP shaft seal failure has been covered extensively elsewhere and will not be repeated here.

FAILURE MODE MODELLING

LPFTP Shaft Seal System Failure. The LPFTP shaft seal system prevents the relatively hot hydrogen gas which drives the low pressure turbine from mixing with the liquid hydrogen being driven through the low pressure pump. The seal system consists of two seals. One is a labyrinth seal located at the base of the second stage turbine blade. The other is a single ring seal on the shaft itself. Since both of these are clearance type seals, a small amount of leakage occurs even during normal operation. This value is approximately 0.49 lbm/sec. Using the perfect gas assumption the flow through the labyrinth seal may be written as

$$m_{lab} = \pi C_D d \cdot c_{lab} P_{lab} \sqrt{\frac{g_c}{R T_{lab}}} f(PR)$$

where $C_D$ is the discharge coefficient, $d$ is the turbine disk diameter, $c_{lab}$ is the seal clearance, $g_c$ is the gravitational constant, $R$ is the real gas constant, $T$ and $P$ are the LPFTP turbine inlet temperature and pressure respectively, and $PR$ is the pressure ratio across the seal, i.e., $P_{exit}/P_{lab}$. In this equation $f(PR)$ has the form

$$f(PR) = \sqrt{\frac{1 + PR^5}{5 - \ln(PR)}} \ .$$

Assuming adiabatic flow and choked conditions, the flow through the ring seal may be written as

$$m_{ring} = 0.685 \pi C_D d \cdot c_{ring} P_{exit} \sqrt{\frac{g_c}{R T_{lab}}}$$

where $d$ and $c_{ring}$ now correspond to the shaft diameter and the ring seal clearance respectively. The multiplicative constant 0.685 is obtained using a specific heat ratio for hydrogen gas of 1.4. Assuming a common discharge coefficient of 0.9 for both seals and disk and shaft diameters of 6.0 and 2.0 inches respectively, equations 1 and 3 may be equated and the common terms eliminated to obtain
This equality cannot be rearranged to obtain an analytical expression for the pressure ratio \( \text{PR} \) as a function of clearance due to the nature of \( f(\text{PR}) \). However, an approximation can be obtained by expanding equation 4 in a Taylor series about \( \text{PR} = 1 \). The result is

\[
\text{PR} = 2.0 \left( 1 + \sqrt{1 + 1.75 \beta(\text{PR})} \right) / \beta(\text{PR})
\]

where \( \text{CR} = \frac{\text{cring}}{\text{clab}} \) and \( \beta(\text{CR}) \) is

\[
\beta(\text{CR}) = 1.303 \text{CR}^2 + 7.0.
\]

Thus with the clearance of each seal known, and the LPFTP turbine inlet state known, equation 5 may be used to obtain \( \text{PR} \). With \( \text{PR} \) known, \( P_{\text{exit}} \) is known, and equation 3 may be used to obtain the flow rate through the seal.

The clearance of the ring seal must be specified and a failure of the system is initiated by using a clearance which is much larger (approximately a factor of ten for the demonstration) than the nominal value which is assumed to be 3 mils. The clearance of the labyrinth seal depends upon the speed of the turbine. Specifically, the governing equation may be written as

\[
\text{ci}_\text{lab} = 0.005 \omega (\omega^2 - a_2)
\]

where \( \omega \) is the turbine shaft speed in rad/sec. The constants \( a_1 \) and \( a_2 \) where chosen such that the clearance is 5 mils at 100 percent power and 0 mils at full power.

The LPFTP shaft seal model has been implemented on the real time SSME simulation by introducing these equations into the code. The mass flow rate through the seal system was subtracted from the low pressure fuel turbine discharge mass flow and added to the pump discharge mass flow. The pump discharge temperature was modified to account for the hot gas mixing with the cold liquid. Figures 2a, 2b, and 2c show the open loop response of the shaft seal failure at rated power. Chamber pressure was insensitive to the shaft seal failure, and has been omitted. The seal degradation is shown on all plots to occur at four seconds and take place over a two second interval at a constant ramp rate. For the failure shown, the leakage rate from the turbine to the pump increased from a nominal 0.486 lbm/sec to 1.66 lbm/sec causing a decrease in the LPFTP pump discharge pressure shown in Figure 2a as the turbine pumps less fuel from the tank. Figure 2b shows how the increase in hot gas entering the cool fuel from the supply tank results in a slight increase in pump discharge temperature. Both the discharge pressure and temperature along with the volumetric fuel flow from the pump and chamber pressure are used to estimate the mixture ratio in the main combustion chamber. Figure 2c shows how the relatively minor leakage causes the mixture ratio estimate to degrade. The degradation is caused by the relatively large drop in the pump discharge pressure. The poor mixture ratio causes some difficulties for the multivariable control approach and is discussed in some detail later. The LPFTP shaft seal failure model provides the qualitative behavior of interest for closed loop analysis and development of accommodation strategies.

**LPFTP Turbine Tip Seal Failure.** Turbine tip seals are designed to prevent leakage of gas between the outside ends of the turbine blades and
the turbine casing. The rate of leakage which occurs in this region is generally very small compared to the total flow through the turbine; however, the effect on performance can be significant. The fluid leaking around the tip of the turbine blade disturbs the flow field on the rest of the aerofoil in a manner similar to crossflow over an airplane wing. This results in reduced lifting capacity of the blade and therefore reduced efficiency of the turbine. In order to prevent this effect, turbine blades are often shrouded on the ends. The shroud reduces the crossflow and subsequent sensitivity to tip leakage. Furthermore, the shroud is typically equipped with a labyrinth type tip seal which cuts down significantly on the leakage flow. The HPFTP does not have shrouded blades however, due to high speed and inlet temperature. Sealing is therefore affected by maintaining as small a clearance as possible between the blade tip and the housing. A seal failure represents a change in this clearance to some value significantly larger than the design value. Experiments demonstrate that the relationship between turbine efficiency and tip clearance is generally linear; however, the slope is strongly dependent on the number and degree of reaction of the turbine stages. Although it has been determined to be a relatively likely failure, no actual mention of the cause of the tip seal clearance change has been made or the degree of clearance change that is expected. Figures 3a, 3b, and 3c demonstrate the qualitative behavior of this failure in an open loop simulation of the real time SSME model for a 10% ramp decrease in turbine efficiency beginning at four seconds. Figure 3a shows a relatively slight decrease in chamber pressure resulting from the decrease in the HPFTP pump discharge pressure. The pump discharge pressure drops because the turbine is doing less work on the fluid for the given preburner temperature. Figure 3b shows both the estimated and actual MRs rising because of the drop in fuel being pumped by the HPFTP. Notice the slight degradation in the MR estimate as the failure propagates to its full value at six seconds. This degradation in the estimation scheme does not cause difficulties with the MVC as in the case discussed above. Figure 3c shows a dramatic rise in the HPFTP discharge temperature resulting from the decrease in the turbine's ability to remove energy from the hot gas of the preburner. The open loop responses shown in these figures typify behavior for a decrease in efficiency of the high pressure fuel turbine and coincide with our physical understanding of the failure and its impact on performance parameters.

CONTROLS AND COORDINATION

The control and coordination functions lie at the heart of the intelligent control system. Selection of failure modes for an on-line diagnostic system is driven by the ability to accommodate such failures or degradations in hardware using existing sensing and actuation. Additional sensing and actuation hardware may be considered by weighting expected costs against benefits in conjunction with the likelihood of the failure occurring and the effect if left unattended. For this work, an additional actuator was selected for inclusion in an engine model based on recommendations from a study performed by Rocketdyne under contract to NASA LeRC. In addition, the instrumentation set on the Marshall Space Flight Center Technology Test Bed is assumed.

NOMINAL MULTIVARIABLE CONTROLLER

Control of the SSME is accomplished through five valves shown in Figure 4. In particular, the Main Oxidizer Valve (MOV), Main Fuel Valve (MFV), Coolant Control Valve (CCV), Oxidizer Preburner Oxidizer Valve (OPOV), and
Fuel Preburner Oxidizer Valve (FPOV) are open loop scheduled to perform the startup and shutdown operations. In the actual SSME controller (Block I), only FPOV and OPV are used as closed loop control valves for mainstage operation. To analytically explore the benefits of enhanced engine controllability, the Oxidizer Preburner Fuel Valve (OPFV) was added while the previous five valves were also considered for closed loop control during mainstage.

A number of measurement locations are shown in Figure 4 which represent a subset of the SSME test bed sensor suite. The discharge pressure and temperature of the Low Pressure Fuel Turbopump (PL1 and TL1 respectively) as well as volumetric fuel flow (Qfim), and chamber pressure (Pc) are used for estimating mixture ratio (MR) in the existing SSME Block I controller. The discharge pressure of the High Pressure Fuel Turbopump (PH2), the discharge temperatures of the High Pressure Fuel and Lox Turbines (THF2d and THO2d respectively), the pressure of the Fixed Nozzle Heat Exchanger (P4), the pressure of the Main Chamber Heat Exchanger (P3), and the fuel supply pressure of the preburners (P0) are used in conjunction with Pc to form the sensor suite for the multivariable control.

Multivariable control (MVC) methods generally rely on linear state space models of the process to be controlled. A perturbation model of a simplified (39 state) nonlinear dynamic engine model at rated power was used for control design. The linear models of the SSME change very little from the 65% to the 109% power (thrust) level, therefore gain-scheduling was not required. MVC allows the integration of multiple objectives of Pc, Mr, THF2d, and TOT2d command following for example, while decoupling each of the control loops from the others using all six valves in Figure 4 as closed loop control valves.

The nominal controller is designed with the objective of providing the highest degree of fault tolerance and robustness possible for the engine using all available valves and some subset of available sensors while meeting specified performance constraints. Ideally, the sensors selected for state estimation in the state feedback controller would be the most reliable and most accurate of the available instrumentation. However, a performance versus robustness tradeoffs must be made if the most reliable sensors result in a non-minimum phase realization.

A fault tolerant and robust control design for a rocket engine may be achieved in two ways using multivariable control. The first involves designing the controller to be insensitive to variations in the engine, modelling errors, and sensor noise. A variety of formalized techniques for accomplishing this are available in the controls literature based upon the design methodology used. The second involves wisely selecting the variables for closed loop control. For example, a "traditional" control design would allow set point control of both Pc and MR to provide variable throttling and near constant combustion temperature in the main chamber over a range of power levels, respectively. However, for a staged combustion cycle, controlling the discharge temperatures of the high pressure turbines provides a means of regulating the combustion temperatures in the fuel and lox preburners. Moreover, discharge temperatures are redline quantities on the SSME. Redline cutoffs resulting from a decrease in fuel turbine efficiency can be avoided. In general, closed loop control of redline variables may widen the envelope of operation for the engine allowing greater flexibility for off design operation. Consequently, a fault tolerant multivariable control design can be achieved by including THF2d and TOT2d in the controlled variable list along with Pc and MR for the set point controller. However, there may be a better choice given typical variations in engine builds and the difficulty of providing consistent and accurate measurements of turbine discharge temperature. The final selection must depend upon the practical aspects of implementing such a design on a flight system.

RECONFIGURABLE CONTROL

The notion of altering the structure of the controller to accommodate changes in the plant is very attractive for
fault tolerance. Much work has been done in the area of aircraft survivability in combat situations with a focus on actuator failures resulting from battle damage. However, most approaches are heuristic in nature due to the difficulty in generalizing results from a specific application and vary between apriori and on-line designs. A common theme is to distribute the control effort for a failed actuator over the remaining, hopefully somewhat redundant actuators in the system.

The SSME has six valves while the nominal engine controller has only four parameters as controlled quantities. Therefore, it would appear that the engine has two redundant valves for independent control of Pc, MR, Thr2d and Tot2d during mainstage operation since the input matrix of the design model is not rank deficient. However, the nominal control design does not use MOV or MFV for mainstage operation since these two valves are primarily for startup and shutdown. In fact, MOV and MFV are kept wide open for all power ranges encountered during mainstage operation in the Block 1 controller. Therefore, it was concluded that these valves should not be moved for nominal engine operation by increasing the control weighing in the multivariable design. However, these valves can play a major role in accommodating a failure in one or more of the primary control valves (FPOV, OPOV, CCV and OPFV).

One approach for control reconfiguration for actuator failures is shown in Figure 5. The basic idea is to design a controller for each of the failure conditions and then switch designs once the failure is identified by the online diagnostic system. For example, if the position of FPOV sticks at a certain time in the mission, then a control law (u_{pov}) designed without the column corresponding to FPOV in the B matrix of the design plant is blended with the nominal control (u_{nom}) to give the applied control (u_{app}) as

\[ u_{app}(t) = (1-\lambda(t)) u_{nom}(t) + \lambda(t) u_{pov}(t), \text{ where } \lambda(t) \in [0,1]. \]  

As shown in the figure, the nominal and off-nominal control designs run in parallel to minimize startup transients associated with switching between controllers. The approach is straightforward from both a conceptual and implementation standpoint. The difficulty is selecting an acceptable blending rate \( \lambda(t) \) between the nominal control and the new control for the failure condition. Once the new controller is active, the closed loop performance and robustness are known from the apriori design. However, the approach has several short comings. The most significant being the high number of parallel controllers of order \( N \) for a potentially large number of failure scenarios \( M \) resulting in a control system of order \( N^2M \) making implementation of such a system in flight hardware somewhat impractical. Another potential problem involves integrator windup for each of the controllers running in parallel but "off-line". Windup may result in transients of the kind we hoped to avoid by running the controllers in parallel in the first place. However, this behavior has not been a problem to date and can be minimized further by ramping between controllers more slowly. The approach taken is not a panacea, however it does allow us to explore the potential benefits of using control reconfiguration in a relatively straightforward way.

**ENGINE LEVEL COORDINATOR**

The engine level coordinator may change the setpoints of the currently controlled variables to meet performance constraints, avoid detrimental operating conditions, change the controlled variables (i.e. mode switching), or select an alternate control structure to accommodate a failed or degraded component in the engine system as summarized by Figure 5. Moreover, degradations or failures of certain engine components may adversely affect performance limits. In this situation, the coordinator must recompute new limits based on information provided by the on-line diagnostic system. The engine level coordinator is responsible for meeting thrust and MR requirements set by the propulsion level to the extent possible while avoiding an engine shutdown condition. Engine shutdown is determined by the propulsion level coordination based on information provided by the engine level coordinator, relative health of the remainder of the propulsion system, and mission safety requirements. Information about the health of the engine and the necessary performance parameters are supplied to the propulsion coordinator to aid decision making at that level about each engine's thrust and MR.

A bottom up strategy has been adopted to develop algorithms for use in the engine level coordinator. For the
The simulation results for job the FPOV is mission with a new control throughout the remainder of the approach outlined above. Once control engine and initiates control btendi,lg using coordinator generates new maximum possible Pc for valve, failure and estimated the ignoring use of nonfinal control does loss of mission if an accommodation loading mission FPOV response provides better control of MVC has MR tmarginally repeated level modelling efforts have not progressed to tile Figure 5 Multivariable Reconfigurable Control Scheme avoid further degradations. However, our parameters, failures multivariable alternative coordination, shaft seal failure in commands9 thereby reaches a balance without any explicit changes Tft2d, activity by changing tip new position of the stuck valve and provide this maximum decrease maximum achievable thrust some point during tile Max coordination activity. If \( \text{for } FPOV \text{ Sticking. } \)

The sticking of the FPOV during the thrust bucket of the SSME mission could result in extreme structural loading on the orbiter vehicle with possible loss of mission if an accommodation strategy does not allow completion of the transient. To accomplish the accommodation, an off nominal control may be designed which makes use of the remaining valves (OPOV, MOV, MFV, CCV, and OPFV) to provide closed loop control of MR and Pc while ignoring turbine discharge temperatures. Once the on-line diagnostic system has diagnosed the failure and estimated the position of the failed valve, the coordinator can compute the maximum possible \( \text{Pc} \) for the engine without forcing MR off nominal (6.011). The coordinator generates new commands for the engine and initiates control blending using the approach outlined above. Once control reconfiguration is complete, the off nominal control provides variable throttling and MR control throughout the remainder of the mission with a new limit on maximum thrust for that engine.

The off-nominal controller without the FPOV is synthesized using the same control Figure 6 Chamber Pressure Response for Thrust Bucket with Valve Failure

**ACCOMMODATION STRATEGIES**

Accommodation strategies have been developed for the sticking of FPOV and the HPFTP turbine tip seal failure. The simulation results for accommodation of the turbine tip seal failure have been published elsewhere[1] and will not be repeated here. Further work is required for the LPFTP shaft seal and possibly the HPOTP shaft seal system. The MVC is marginally unstable for a nontrivial leakage in the LPFTP shaft seal when using the MR estimation algorithm developed for the Block I control. The reason for this has roots in the differing design philosophies between Block I and the MVC. The MVC has MR as the "fast" control loop while the Block I control as Pc as the "fast" loop. Having MR as the faster loop provides better control of temperature deviations in the engine cycle and results in a lower order controller since the MR response is much slower than Pc. Oscillations in the MR response result from the impact of the LPFTP shaft seal failure on the quality of the MR estimate as shown earlier in Figure 3a, while the Block I control experiences no difficulty in regulating Pc and MR. Work is in process to develop an alternative MR scheme using a kalman filter to alleviate the marginal instability with the MVC. Figure 5 Multivariable Reconfigurable Control Scheme

**FPOV Sticking.** The sticking of the FPOV during the thrust bucket of the SSME mission could result in extreme structural loading on the orbiter vehicle with possible loss of mission if an accommodation strategy does not allow completion of the transient. To accomplish the accommodation, an off nominal control may be designed which makes use of the remaining valves (OPOV, MOV, MFV, CCV, and OPFV) to provide closed loop control of MR and Pc while ignoring turbine discharge temperatures. Once the on-line diagnostic system has diagnosed the failure and estimated the position of the failed valve, the coordinator can compute the maximum possible \( \text{Pc} \) for the engine without forcing MR off nominal (6.011). The coordinator generates new commands for the engine and initiates control blending using the approach outlined above. Once control reconfiguration is complete, the off nominal control provides variable throttling and MR control throughout the remainder of the mission with a new limit on maximum thrust for that engine.

The off-nominal controller without the FPOV is synthesized using the same control Figure 6 Chamber Pressure Response for Thrust Bucket with Valve Failure

---

**Figure 5 Multivariable Reconfigurable Control Scheme**

**Figure 6 Chamber Pressure Response for Thrust Bucket with Valve Failure**
structure, design methodology and sensor suite employed with the nominal controller. Control of MR without using the FPOV is a very difficult task since the MR response depends heavily on this valve. In fact, the Block I control uses FPOV exclusively for MR regulation. The design procedure resulted in a controller of the same order as the nominal control and uses four valves (OPOV, CCV, OPFV and MPV) to decouple the MR from the \( P_c \) response. Theoretically, decoupling using fewer valves is possible. However the objective was to demonstrate the capability of recovering from a failure in a primary control valve while preserving control of \( P_c \) and MR. The off nominal control performs satisfactorily over mainstage without gain scheduling as does the nominal control.

Figures 6 and 7 show the \( P_c \) and MR responses for the thrust bucket maneuver, respectively. Figure 6 includes five curves with two sets of two being identical until approximately the eleven second mark and are highlighted with a rectangle. The coordinated and uncoordinated MVC and thrust command demonstration the importance of the engine level coordination. The Block I controller response is included for reference purposes to motivate the need for accommodation. The failure of FPOV occurs at exactly three seconds into the transient when the valve locks up. The responses shown assume identification takes place instantly which is certainly unrealistic. The plots show the best you can do with the reconfigurable MVC. Any delay in identification will degrade the performance of the accommodation scheme. Very little perturbation is seen during accommodation of the valve by the MVC while the Block I control is smooth since OPOV is responsible for \( P_c \) control. Figure 7 shows the degradation in MR control when the valve sticks for both MVC and Block I. However, reconfiguration of the MVC by four seconds (blending) begins to return MR to the design point while the Block I response shows the coupling between \( P_c \) and MR.

If the coordinator does not lower the maximum \( P_c \) for the engine based on the position of FPOV then the responses shown for the "Uncordinated MVC" result. Figures 6 and 7 show the tradeoff between \( P_c \) and MR when "too much" thrust is requested from the engine. Neither \( P_c \) or MR can meet demand, therefore the MVC balances the errors based upon the relative weights used in the design procedure. The imbalance is exemplified by the Block I control which meets requested thrust while MR in Figure 7 increases to 7% over nominal. If coordination takes place, then the responses labelled "Coordinated MVC" result. Figure 6 shows how a decrease in demanded thrust for the MVC can be achieved while keeping MR in Figure 7 at or about the nominal setting. A decrease in demanded thrust by a particular engine in a propulsion system can be compensated for by other "healthy" engines in the cluster without compromising the mission.

**INTELLIGENT CONTROLS GRAPHICAL USER INTERFACE**

The Graphical User Interface (GUI) was developed to allow the ICS to be monitored during operation. The GUI permits operators to observe the ICS in real-time operation as it accommodates faults in components, sensors, and actuators, using a collection of screens designed to provide a clear illustration-through plots, text, and animation-of the entire process. The GUI is a full-color, object-oriented system consisting of a set of screens arranged hierarchically. Each screen consists of three windows: a mouse-sensitive graphical display window containing a diagram of a component or system, a plotting window depicting time responses of key variables associated with that component or system, and an interactive type-out window displaying messages and allowing the user to enter commands. When the mouse pointer is over the selectable object in the mouse-sensitive graphical display window, a box appears around the object and its name is displayed at the bottom of the screen. Clicking on it brings
up the screen corresponding to the object. The hierarchy of screens may be viewed in this manner. Figure 8 shows an example screen. The top window contains a view of the space shuttle main engine composed of selectable objects, the window on the lower left displays messages, and that on the lower right displays plots. One of the components is selected as indicated by the box around it and its name is displayed in the lower left corner of the figure. The GUI plots time responses of important variables and indicates failures to the user through messages in the type-out window and by causing failed mouse-selectable components to flash. The user may bring up more detailed screens by clicking on the objects. Because of the modular, object-oriented nature of the GUI, the creation of additional screens is simple and quick. Thus appropriate screens can be added easily as more failure modes are incorporated into the testbed system.

SUMMARY

Demonstration of an Intelligent Control System for reusable rocket engines (SSME) is on-going at NASA LeRC. To facilitate this process, a preliminary subset of failure modes was selected from the set of all accommodatable failure modes. In particular, failure of a control sensor (Pc), a frozen Fuel Preburner Oxidizer Valve, a Low Pressure Fuel Turbo Pump shaft seal failure, a High Pressure Fuel Turbo Pump turbine tip seal failure, and a High Pressure Oxidizer Turbo Pump shaft seal failure were selected. Due to the requirement of accommodating engine failures or degradations, hot fire data cannot be used in closed loop evaluation and serves to validate health monitoring algorithms only. Consequently, a modelling effort is ongoing to study the effects of the failures on SSME performance and some results to date have been included. Modelling has focused on first order effects and little attention has been paid to the propagation of failures or the potential negative impact of off nominal operation of the engine and subsequent failures. These are important issues, however our focus is constrained given available resources to address this complex problem. The failure models are used to study the behavior of the engine as a failure occurs during closed loop operation with a nominal engine controller. If unacceptable behavior results, the operating point or the set of controlled variables or both is changed to accommodate the problem by the engine level coordinator. If none of these actions resolves the anomalous behavior, an alternate control design is performed offline to meet the requirement of fault tolerance. A reconfiguration scheme has been presented which allows switching between predesigned controllers running in parallel based on the identified engine failure. An example using a stuck Fuel Preburner Oxidizer Valve was given to illustrate these ideas on a realtime simulation of the SSME. Results show that successful accommodation of primary control valves can be achieved using control reconfiguration in conjunction with a multivariable design methodology. Finally, the graphical user interface for the Intelligent Control System project was presented which aids the analysis of the system during accommodation of simulated engine failures.

A Demonstration of an Intelligent Control System for a Reusable Rocket Engine

Jeffrey L. Musgrave, Daniel E. Paxson, Jonathan S. Litt, and Walter C. Merrill

An Intelligent Control System for reusable rocket engines is under development at NASA Lewis Research Center. The primary objective is to extend the useful life of a reusable rocket propulsion system while minimizing between flight maintenance and maximizing engine life and performance through improved control and monitoring algorithms and additional sensing and actuation. This paper describes current progress towards proof-of-concept of an Intelligent Control System for the Space Shuttle Main Engine. A subset of identifiable and accommodatable engine failure modes is selected for preliminary demonstration. Failure models are developed retaining only first order effects and included in a simplified nonlinear simulation of the rocket engine for analysis under closed loop control. The engine level coordinator acts as an interface between the diagnostic and control systems, and translates thrust and mixture ratio commands dictated by mission requirements, and engine status (health) into engine operational strategies carried out by a multivariable control. Control reconfiguration achieves fault tolerance if the nominal (healthy engine) control cannot. Each of the aforementioned functionalities is discussed in the context of an example to illustrate the operation of the system in the context of a representative failure. A graphical user interface allows the researcher to monitor the Intelligent Control System and engine performance under various failure modes selected for demonstration.
