July 1992
A mathematical model and associated computer program (f18bas) to simulate a twin-tailed high performance fighter airplane (McDonnell Douglas F/A-18) are described. The simulation is intended to support advanced control law research for application to high performance aircraft. The modeled flight envelope is extensive, allowing investigations in the high-angle-of-attack portion of the flight regime. Included in the simulation mathematical model are the nonlinear, six degree-of-freedom rigid-body equations, an engine model, and simple sensor and actuator models. A simplified form of the F/A-18 digital control laws (version 8.3.3) is implemented, including only the Auto Flap Up (AFU) flight mode used for air combat maneuvering. Aerodynamic forces and moments are calculated from a wind-tunnel-derived database using table look-ups with linear interpolation. The aerodynamic database has an angle-of-attack range of -10° to +90° and a sideslip range of -20° to +20°. Elastic deformation effects are incorporated in a quasi-static-elastic manner, with no dynamic simulation of the elastic degrees of freedom.

1. INTRODUCTION

The mathematical model and associated computer program (fl8bas) to simulate a twin-tailed high performance fighter airplane (McDonnell Douglas F/A-18) are described. The simulation is intended to support advanced control law research for application to high performance aircraft. The modeled flight envelope is extensive, allowing investigations in the high-angle-of-attack portion of the flight regime. Included in the simulation mathematical model are the nonlinear, six degree-of-freedom rigid-body equations, an engine model, and simple sensor and actuator models. A simplified form of the F/A-18 digital control laws (version 8.3.3) is implemented, including only the Auto Flap Up (AFU) flight mode used for air combat maneuvering. Aerodynamic forces and moments are calculated from a wind-tunnel-derived database using table look-ups with linear interpolation. The aerodynamic database has an angle-of-attack range of -10° to +90° and a sideslip range of -20° to +20°. Elastic deformation effects are incorporated in a quasi-static-elastic manner, with no dynamic simulation of the elastic degrees of freedom. In the engine model, the throttle-commanded steady-state thrust level and the dynamic response characteristics of the engine are based on airflow rate as determined from a table look-up. Afterburner dynamics are switched in at a threshold based on the engine airflow and commanded thrust. The control surfaces are driven by simple transfer functions with constant rate and position limiting.

1.1 Comments on ACSL

The simulation program written in the Advanced Continuous Simulation Language (ACSL). The ACSL simulation system, described in ACSL (1987), consists of a special purpose high level language, a translator, and various libraries to satisfy the commands available in the language. ACSL functions according to specifications established under the auspices of Simulation Councils, Inc. in 1967 [Format Subcommittee (1967)]. In a typical application of the ACSL system, a simulation model is first constructed using the special ACSL language. A translator is invoked that converts a model written in ACSL to Fortran 77 code. Fortran subroutines can be called from the simulation model with certain restrictions. The Fortran code is compiled and linked with the ACSL libraries. The resulting executable program will prompt for user input and produce plots and printed output.

1.2 Simulation Development History

In 1986, a team was established at the NASA Langley Research Center to address some of the control-related problems of designing highly integrated aircraft. This team was composed of members of the Aircraft Guidance and Control Branch and the Aeroservoelasticity Branch at LaRC and was dubbed the Functional Integration Technology (FIT) team. The focus of the FIT team's effort was highly maneuverable aircraft with minimal structural weight. It was anticipated that such aircraft would require active structural control. The original focus vehicle was the X-29 research airplane. About 6 months after the FIT team was formed, the focus vehicle was changed to the F/A-18. Focusing on an F/A-18 allowed the FIT team to leverage off NASA's High Angle-of-Attack Research Vehicle (HARV) program. Because of the HARV program, NASA would own a preproduction F/A-18 aircraft that would be used in an extensive flight test program. The X-29, on the other hand, was a joint program over which NASA had less control.

One of the first tasks of the FIT team was to develop a simulation of an F/A-18 that incorporated: (1) nonlinear, six degree-of-freedom, rigid body dynamics, (2) linear elastic modes, and (3) unsteady aerodynamics. At that time the team had access to a batch simulation computer program (mdcf18) and documents written by the McDonnell Aircraft Company of the McDonnell Douglas Corporation (MDC) for the F/A-18. The mdcf18 simulation was a complete, nonlinear, six degree-of-freedom batch simulation that ran on a Digital Equipment Corporation VAX computer. The mdcf18 simulation included the 8.3.3 flight control system, hinge-moment calculations, and a
full aerodynamic database. A considerable portion of the \textit{mdcf18} simulation was devoted to failure modes of the propulsion and actuation systems. The FIT team also had access to a real-time simulation computer program of an F/A-18 that executed on a CDC Cyber 175 and was written by Unisys personnel for use with the Differential Maneuvering Simulator (DMS) at LaRC. The LaRC-DMS real-time simulation (\textit{dmsf18}) was derived from the MDC simulation and documents provided by MDC. The FIT team chose to focus on dynamics issues rather than failure modes. There was also a requirement to interface closely with the LaRC real-time facilities and to begin setting up procedures whereby the transfer of specifications and code between researchers and the real-time simulation software development staff could be streamlined. The original FIT F/A-18 simulation [Arbuckle, et al. (1987) and Buttrill, et al. (1987)] was a batch simulation written in ACSL that included 6 nonlinear degrees-of-freedom and 20 elastic degrees-of-freedom, but no control system. The rigid-body aerodynamic model and the engine model of the original FIT F/A-18 simulation were largely derived from the LaRC DMS real-time simulation (\textit{dmsf18}).

Another research focus at LaRC is agility at high angle-of-attack and low-to-moderate dynamic pressures. To support researchers working in this area, the fully elastic simulation developed by the FIT team was modified. The elastic dynamics were removed. The code that simulated the 8.3.3 flight control software in the LaRC-DMS real-time simulation was obtained and interfaced with the ACSL batch simulation. This report describes the resulting simulation code (\textit{f18bas}).

The initial simulation code (\textit{f18bas}) developed to support the Aircraft Guidance and Control Branch's high-angle-of-attack research was frozen so that this document could be written. The \textit{f18bas} simulation models a preliminary-design version of the thrust-vectoring system proposed for the HARV program. The preliminary-design thrust vectoring system employed two paddles per engine nozzle, whereas the actual system subsequently installed on the HARV demonstrator has three paddles per nozzle. The thrust vectoring capability of the \textit{f18bas} simulation will only be described in a limited fashion as required to explain parameter lists. The simulation model without thrust-vectoring can be recovered by setting the logical, \texttt{LTHVEC}, to false.

One outgrowth of the \textit{f18bas} simulation was the \textit{f18harv} simulation. The \textit{f18harv} simulation represents the Aircraft Guidance and Control Branch's best current model of the HARV demonstrator. The mathematical model for \textit{f18harv} simulation is documented in a variety of internal memoranda and will be more formally described in a future report.

### 1.3 Code Development Philosophy

ACSL allows one to call Fortran subroutines from within ACSL source code. Since ACSL source code gets translated into Fortran before compilation, this is not surprising. If one chose, the calculation of all the state derivatives could be done in a Fortran subroutine. The derivatives could be returned as outputs from the subroutine and integrated by ACSL. ACSL could plot and record variables in the parameter list. The equations of motion would then be a black box. Linear analysis on the ACSL-integrated states could be performed. Alternatively, if one had an existing Fortran simulation, the entire Fortran simulation could be made into a subroutine and treated as, from the perspective of ACSL, a discrete process that returned outputs at current time, \(t\), based on inputs at a previous time, \(t-h\). The states of the Fortran subroutine would be hidden from ACSL and none of the linear analysis capability of ACSL could be used.

The goals adopted by the authors for building the simulation were: (1) all integrations arising from continuous processes would result in ACSL-defined states, and (2) the equations of motion, to the extent possible, would be coded in the ACSL language. Goal (2) was compromised slightly in that the calculation of aerodynamic forces and moments and engine steady state performance are done in Fortran subroutines. The authors had available software that greatly facilitated creating code to implement large table look-up type databases characteristic of aerodynamic force and moment.
build-ups and the ACSL capabilities in this area are limited. Since not everyone has ACSL, coding the aerodynamic and engine static models in Fortran served to make major portions of the simulation model more accessible to the research community. The continuous dynamics of the simulation include actuator and sensor dynamics, engine dynamics, and the rigid-body equations of motion. Physically discrete dynamics, such as a digital flight control system, are not coded in ACSL. These dynamics are coded in Fortran subroutines and accessed by the simulation through subroutine calls which occur at discrete time increments using the DISCRETE block feature of ACSL. DISCRETE blocks are explained in the next section (Section 2).
2. SIMULATION STRUCTURE

The general structure of an ACSL simulation is described in section 3 of the ACSL reference manual [ACSL (1987)]. Section 2 of this report summarizes key elements of section 3 of the ACSL manual and will cast the specific structure of this simulation in the context of the discussion and figures of the ACSL reference manual.

ACSL imposes some limitations and programming rigor on its users. ACSL works best when the state derivatives are explicitly defined. If absolutely required, the IMPLICIT operator provided by ACSL can be invoked and the resulting simulation will attempt to solve numerically the implicit formulation, but this would result in unacceptable computing performance in all but the simplest models. Implicit loops are best solved by inserting fast filters or solving them algebraically.

ACSL creates a large common block (ZZCOM) that contains all the simulation variables. Included in ZZCOM are three arrays: the state array, the state derivative array, and the state initial condition array. A state is the output of an integration. A state variable in the state array cannot also be in the state derivative array.

2.1 Overview

The ACSL code structure shown in figure 2.1 is somewhat generic yet also contains the salient features of the F18 simulation. The DYNAMIC...END block of figure 2.1 results in the main simulation loop. The main simulation loop is indicated by the lower shaded box in the overview flow diagram of figure 2.2. In the main loop, if the termination condition, \( T > T_{\text{STP}} \), is not met, the program will integrate forward in time over one communication interval, \( C_{\text{INT}} \) [ACSL (1987)]. The communication interval determines how often the code in the dynamic block that is not part of the derivative block or the discrete blocks gets executed. The default value for \( C_{\text{INT}} \) in the fl8bas simulation is 0.025 (1/40) seconds.

The maximum integration step for the DERIVATIVE block is defined by \( M_{\text{XSTP}} \) in the fl8bas simulation and has a default value of 0.00625 (1/160) seconds. The integration algorithm is selected by setting IALG. A variety of integration schemes are offered (IALG = 1 through 7) and are described in ACSL (1987). The default choice for fl8bas simulation is IALG=4, a Runge-Kutta second-order method. The Runge-Kutta second-order method was recommended by the author of ACSL for most mechanical systems and has been found to work satisfactorily. No systematic investigation of integration methods has been made for this simulation. Using the Runge-Kutta second-order method, two derivative evaluations are made to advance time over one integration step, \( M_{\text{XSTP}} \).

The DISCRETE blocks are executed according to their INTERVAL or SCHEDULE statements. DISCRETE block \( \text{name1} \) in figure 2.1 is an example of an interval block that gets executed every \( T_{\text{name}} \) seconds. DISCRETE block \( \text{name2} \) in figure 2.1 is executed whenever the logical condition defined in its SCHEDULE command becomes true. This type of block might be used to reverse the velocity of a ball bouncing on a table. In the fl8bas simulation, the digital control law DISCRETE block, FCS, is an INTERVAL block and is called every \( T_{\text{FCS}} \) seconds. The default value for \( T_{\text{FCS}} \) is 0.025 seconds. The choice of a value for \( T_{\text{FCS}} \) is discussed in section 9 of this report. When different blocks are scheduled for execution at the same time on the event list, such as when a DISCRETE block interval is an even multiple of \( M_{\text{XSTP}} \) or some other DISCRETE block interval, the order of execution is determined by order of appearance in the model definition code. It is not required that the DISCRETE interval period be a multiple of the maximum integration size for the DERIVATIVE block. An INTERVAL type DISCRETE block sets up a time barrier on an event list. ACSL will shorten the last integration step to insure all simulation variables are synchronized at the correct interrupt time.
Figure 2.1. Outline of Typical ACSL Program

The paths in figure 2.2 associated with the variables LTR, ITFLG, LWRTR and LDBTR arise from code installed to trim the simulation. This path does not arise from any of the typical ACSL constructs found in figure 2.1. The trim logic is discussed in more detail in section 2.2 and figure 2.4 of this report.
Figure 2.2. Overview of Simulation Flow
Call subroutine LOAD. LOAD reads in trim input file, "PI8TR", and calls subroutines that initialize zero and engine data arrays stored in common blocks.

1. Set actuator state IC's to control surface position commands determined by the trim search.
2. Set engine state IC's to commands from trim search. Insures engines in steady state at t=0.
3. Compute steady-state sensor outputs.

Execute code in DYNAMIC...END block not contained in DERIVATIVE or DISCRETE blocks.

Evaluate Discrete Code Blocks

- DISCRETE.FCS END
- DISCRETE.FDT END
- DISCRETE.ABR END
- DISCRETE.ABL END

Initialize integration routine by transferring the state IDC's to the states and calling the derivative evaluation code.

Execute DERIVATIVE...END code block.

Integrate over the communication interval, CINT. Call DERIVATIV and DISCRETE code blocks as required.

Write variables on the OUTPUT and PRIPAR lists to units DIS and PRN.

Evaluate Discrete Code Blocks

Write variables on the OUTPUT and PRIPAR list variables to units DIS and PRN.

Return to ACSL executive: ACSL>

Figure 2.3. Initialization and Discrete Block Details
In figure 2.3, two sections of the simulation flow shown in figure 2.2 are expanded. The actions produced by calling subroutine LOAD in the INITIAL...END code block are detailed and the four discrete blocks in the simulation are shown. The discrete blocks that model the flight control system (FCS) and provide a mechanism for making comparisons with flight data (FDT) are invoked by INTERVAL commands. The discrete blocks associated with the engine afterburner models (ABR & ABL) are invoked by SCHEDULE statements.

2.2 Finding a Trim Solution

ACSL has a TRIM command that works with purely continuous models. To use the ACSL TRIM command, a subset of the simulation states (outputs of integrations) is selected using the command

\[
\text{ANALYZ 'CLEAR','RELEAS' = \{ state list \}.}
\]

The ACSL trim function works by adjusting the selected states until their state derivatives are zero. A combination of a Newton step and a steepest descent step is used (section 5.2.4 of ACSL (1987) to adjust the states. Without some modification, this is not what one generally wants in an airplane trim problem. For example, a simple longitudinal level-flight trim problem might be:

\[
\text{Find, } \quad \{ u \} = \{ \delta_e, T, \alpha, \theta \}
\]

such that

\[
\{ y \} = \{ \alpha, V, q, H \}
\]

for fixed \( V \) and \( H \), where \( \delta_e, T, H, \alpha, \theta, V, q \) are elevator deflection, thrust, altitude, angle-of-attack, pitch angle, total airspeed and pitch rate, respectively.

In this case, elevator deflection and thrust are control inputs, and altitude, angle-of-attack, pitch angle, total airspeed and pitch rate are states. Trying to find \( \alpha, V, q \) and \( H \) such that \( \{ y \} = \{ 0 \} \) for fixed, arbitrary, values of \( \delta_e, T \) and \( \theta \) is almost always fruitless. To use the ACSL trim capability to solve the trim problem described in equations (2.1) and (2.2), one could add the following equations to the simulation model:

\[
\dot{\delta}_e = k_1 q
\]

\[
\dot{T} = k_2 \dot{V} + k_3 \dot{H}
\]

When attempting to trim, \( k_1, k_2 \) and \( k_3 \) would be set to something nonzero. The states \( \{ \delta_e, T, \alpha, \theta, q \} \) can then be released and the ACSL command "ANALYZ TRIM" invoked. ACSL will then drive \( \{ \delta_e, T, \alpha, \theta, q \} \) to zero and in the process, by virtue of equations (2.3) and (2.4), assure that \( \dot{V}, \dot{q}, \dot{H} \) are zero. Equations (2.3) and (2.4) mimic the idea of a trim button or elevator trim-wheel. Generalizing this procedure to handle additional trim cases, such as trimming in a steady level turn or in a symmetric pull-up, could get cumbersome. In addition, it is not clear whether the ACSL trim feature could be made to work with a discrete-block control law in the loop. For these reasons, the authors chose to implement the alternative trimming strategy shown in figure 2.4. The trim strategy employed in fl8bas is not without drawbacks, and a strong case can be made for retaining the ACSL structure and search algorithms as much as possible.
From executive ACSL> START

ITFLG = 1
Set first pass flag for trim loop.

Call subroutine LOAD. LOAD reads in trim input file, "F18TR", and calls subroutines that initialize aero and engine data arrays stored in common blocks.

(1) Set actuator state IC's to control surface position commands determined by the trim search.
(2) Set engine state IC's to commands from trim search. Insures engines in steady state at t=0.
(3) Compute steady-state sensor outputs.

Call F18FCS to execute control law subroutine and generate actuator commands from pilot inputs and sensor data.

Initialize integration routine by transferring the state IC's to the states and calling the derivative evaluation code.

Execute code in DYNAMIC...END block not contained in DERIVATIVE or DISCRETE blocks.

Integrate over the communication interval, CINT. Call DERIVATIVE and DISCRETE code blocks as required.

Write variables on the OUTPUT and PREPARE lists to units DIS and PRN.

Return to ACSL executive: ACSL>

Initial...END code block

Trim Logic

Trim inner loop that allows implicit loops to settle out.
E.g. y = f(x,y)
Implicit loops are created when LFCS is engaged.

ITR ≤ ITRMX

TRUE

Call TRIM subroutine to generate next set of trial IC's. Return ITFLG to indicate:
(2) trim attempt ongoing
(3) trim successful
(4) trim failed

TRUE

ITFLG = 2

TRUE

ITFLG = 3

TRUE

ITFLG = 4

TRUE

TRUE

ITFLG = 4

TRUE

TRUE

ITFLG = 6

TRUE

TRUE

LVDF

TRUE

Write dictionary listing

TRUE

LWRTR

TRUE

Write new trim solution to F18TR. Set LWRTR false.

Figure 2.4. Trim loop expanded.
Details of the logic used to trim the simulation are shown in figure 2.4. Subroutine TRIM defines an array called XTRIM and an array called YTRIM. The first NXTR elements of XTRIM are varied until the the first NXTR elements of YTRIM are within some tolerance of zero. The allowable elements of XTRIM and YTRIM are shown in tables 2.1 and 2.2, respectively.

</table>
The elements of XTRIM and YTRIM are selected by setting the first NXTR elements of the IXSEL and IYSEL arrays. A typical 4×4 longitudinal open-loop trim case could be set up as indicated in figure 2.5. In this example, Mach and altitude are selected a priori and the variables \( \{ \alpha, \theta, \delta_{Ss}, \text{power setting} \} \) are varied until \( \{ \dot{u}, \dot{w}, \dot{q}, \gamma_{\text{TR}} \} \) are driven to zero.

```
ACSL> NXTR = 4
ACSL> HIC=10000.,MACHTR=.5, GAMTR=0.0,LFCS=.F.
ACSL> IXSEL=3,7,16,18
ACSL> IYSEL=1,3,5,7
ACSL> START
```

Figure 2.5. Trim example 1

Trim example 2 in figure 2.6 is similar except that a trim with the flight control system engaged is sought. The pilot longitudinal stick command is substituted for stabilator position in the list of variables to be varied.

```
ACSL> NXTR = 4
ACSL> MACHTR=.5, GAMTR=0.0,LFCS=.T.
ACSL> IXSEL=3,7,16,14
ACSL> IYSEL=1,3,5,7
ACSL> START
```

Figure 2.6. Trim example 2

Achieving trim requires that all state derivatives are zero, not just the states associated with aircraft motion. The states associated with actuator, sensor, and control law dynamics must be trimmed. For the continuous actuator and sensor states, one approach would be to include these additional states explicitly in the nonlinear trim problem. This would serve to unnecessarily increase the dimension of the trim search. In addition, the trim architecture would become dependent on actuator and sensor transfer functions. For the transfer-function-based dynamics typically associated with actuator and sensors, the calculation of the required state initial conditions to achieve trim for a given input is simple. Therefore, when in the trim loop, the dynamics of the actuator,
sensor, and control system are trimmed locally, not as part of the nonlinear search. Integrators are turned off and steady state values for all filters are calculated and passed through. Actuator and sensor state initial conditions are set so that the state derivatives are zero for the given inputs. However, local trimming of actuator and sensor dynamics creates an implicit loop in the global trim problem when the flight control system is engaged (LFCS set true - see section 9.2). For example, suppose trim pitch stick position (PCSTR) is one of the admissible XTRIM variables. A change in PCSTR produces a change in the control surface commands, which instantaneously produces (since the actuator dynamics are suppressed) a new control deflection. The change in control deflection produces a change in the vertical accelerometer output, $n_{zs}$. Since $n_{zs}$ is a feedback, a change in $n_{zs}$ produces an additional change in the control surfaces, which produces new, slightly different $n_{zs}$. The trim search assumes the following functional relationship:

$$\{Y_{TRIM}\} = f(\{X_{TRIM}\})$$

The effect of the implicit loop is to make $\{Y_{TRIM}\}$ dependent not only on $\{X_{TRIM}\}$, but on the past values of $\{Y_{TRIM}\}$. The degradation the functional relationship will impede or prevent convergence.

The somewhat ad hoc solution adopted by the authors was to implement an inner trim loop to converge the implicit loop (see figure 2.4). The inner loop increments a counter, $ITR$. The program loops through the control and flight dynamics code with constant trim driver and initial conditions values until $ITR = ITR_{MX}$. The default value for $ITR_{MX}$ is 6.

Subroutine TRIM is called after the inner trim loop completes $ITR_{MX}$ passes. The trim routine perturbs the control commands and flight states specified for XTRIM and checks for convergence of the YTRIM values. When convergence is achieved, ITFLG is set to 3. If convergence fails, either because the maximum outer iteration count (MXITR) is exceeded or the sensitivity matrix becomes singular, ITFLG is set to 4. ITFLG will be set back to 1 at the first pass of each run (as shown in figure 2.4), and trimming will occur each time the program is started at the ACSL prompt, unless the variable LTR is set false. If LTR is false, the program will pass once through the initial section and go directly into the main program loop, bypassing the trim loop.

Trim convergence is determined in the ACTRML subroutine, which is called from the TRIM subroutine. The variable TRTOL (default = 0.00005) sets the tolerance criterion for convergence.
3. MASS AND GEOMETRY DATA

3.1 General Arrangement

The general arrangement of a single place F/A-18 is depicted in figure 3.1. This report and the MDC documents listed in the References locate points on the airframe using fuselage station (FS), buttock line (BL), and water line (WL) coordinates. The (FS,BL,WL) coordinates are defined in table 3.1. At the plane of symmetry, the BL coordinate is zero.

<table>
<thead>
<tr>
<th>Table 3.1. (FS,BL,WL) coordinates of figure 3.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>FS = positive aft, inches</td>
</tr>
<tr>
<td>BL = positive out the right wing, inches</td>
</tr>
<tr>
<td>WL = positive up, inches</td>
</tr>
</tbody>
</table>

The F/A-18 is a single place, mid-wing, high performance twin engine fighter capable of carrying a variety of armament loadings. For the F/A-18, the primary mission is that of "Fighter Escort". The Fighter Escort mission loading is two wingtip mounted Sidewinder missiles, two fuselage mounted Sparrow missiles, and the M61A1 gun. Each engine is a General Electric, F404-GE-400 rated at 16,100 lbs of uninstalled, static, sea level thrust. The total internal fuel capacity is 10,860 lbs while 6,732 lbs of fuel can be carried in external tanks. The design load factors are +7.5/-3.0 g's. The design sinking speed at touchdown is 25.1 ft/sec.

A moderately swept wing and a highly swept leading-edge extension (LEX) form the primary lifting surface. Leading-edge and trailing-edge flaps on the wing are used for carrier operations, subsonic maneuvering, and cruise. The flap deflections are scheduled with Mach number and angle of attack to provide improved drag and stability characteristics. All moving horizontal tail surfaces are mounted behind and below the wing to provide positive stability at high angles of attack. Twin vertical fins are both canted out and toed out (figure 3.1).

Pitch control is provided by the horizontal tails. Lateral control is accomplished with a blend of ailerons, differential flaps, and differential horizontal tail. Directional control is provided by a rudder on each vertical fin. A speedbrake is also available for deceleration control in the maneuvering configuration. [MDC A7247, p2-1]

3.2 Sign Conventions

While the (FS,BL,WL) coordinate system is used in various MDC reports and the MDC simulation to locate positions on the aircraft, the equations of motion make use of a right-hand body-fixed frame aligned with the (FS,BL,WL) and typically called the body frame. The body frame origin is at the center-of-gravity (c.g.) of the aircraft and is oriented so thatXB is positive forward, YB is positive out the right wing, and ZB is positive down. For example, a sensor package that is located at (FS, BL, WL) would have the following coordinates in the body frame, 

\[
\begin{bmatrix}
X_{B\sigma} \\
Y_{B\sigma} \\
Z_{B\sigma}
\end{bmatrix} = \begin{bmatrix}
- (FS_\sigma - FS_{cg}) \\
BL_\sigma - BL_{cg} \\
- (WL_\sigma - WL_{cg})
\end{bmatrix}
\]

(3.1)

where (FS_{cg}, BL_{cg}, WL_{cg}) are the coordinates of the c.g. in the (FS, BL, WL) axes system.
The body frame, along with the stability frame, control surface sign conventions, and coefficient sign conventions, is depicted in figure 3.2. The stability frame is denoted by the subscript "S" in 3.2. A rotation of $\alpha$ of the stability frame about the $Y_S$ axis brings the stability and body frames into alignment. The roll, pitch and yaw aerodynamic moment coefficients, $C_\alpha$, $C_m$ and $C_n$, are defined about body frame axes, $X_B$, $Y_B$, and $Z_B$, respectively. The lift, drag, and side force coefficients, $C_L$, $C_D$ and $C_Y$, are defined as positive along the $-Z_S$ axis, the $-X_S$ axis and the $+Y_S$ axis, respectively. Note that $Y_S$ is aligned with $Y_B$.

![Figure 3.2. Axis System and Sign Convention](image)

The control surface sign conventions, depicted in figure 3.2, apply to each member of a control surface pair and are described in table 3.2.

3.5 Weight, Center of Gravity, and Inertia Data

The weight, center-of-gravity location, and mass distribution data for the default simulation configuration and for a fighter escort configuration are shown in Table 3.5. The fighter escort description, along with several others, is found in figure 2.3-1 of MDC report A7247. The default configuration represents an early estimate of an F18 HARV configuration after the addition of thrust vectoring hardware. Of all the configurations listed in figure 2.3-1 of MDC report A7247, the data for the fighter escort configuration with 60 percent internal fuel most closely matches the default values.

<table>

<td>Fighter Escort (60% internal fuel)</td>
<td>31665</td>
<td>457.3</td>
</tr>
</tbody>
</table>

The $I_{xz}$ product of inertia in table 3.5 is defined as the integral over the volume of the aircraft of the product $(xz)$ (body frame coordinates) weighted with the mass density, $\sigma$, of the aircraft. The negative of this quantity is what appears as the $(1,3)$ and $(3,1)$ elements of inertia matrix. Thus,

$$I_{xz} = \iiint \sigma xz \, dV$$ (3.2)

The product $I_{xz}$ is typically positive for aircraft with vertical fins but is negative in this case.
4. EQUATIONS OF MOTION

The derivation of the equations governing the motion of a rigid airplane over a flat, nonrotating Earth has been performed many times in the literature and is not likely to be improved upon here. Readers interested in the derivation of said equations are referred to Etkin (1972) and Roskam (1979). In the FL8bas simulation, mass and inertia properties are constants and do not vary with time. If desired, the mass and inertias could be made functions of fuel load according to data presented in MDC-A7247 and MDC-A8575. Gravity is assumed to be aligned with the +Z axis of a local (Earth) right-handed reference frame fixed at sea level. Gravity is assumed constant over the airplane volume, which results in gravity acting as a force at the center of mass and producing no moments. In fact, gravity is constant with altitude with the default value being the sea level value. A reference frame fixed to the body of the airplane (body frame) is the most convenient for expressing the applied aerodynamic and thrust loads. As indicated in figure 3.2, the body frame origin is at the center of gravity and the frame is oriented so that +X_B is out the nose, +Y_B is out the right wing, and +Z_B is out the belly. The airplane is assumed symmetric about the plane formed by the X_B and Z_B axes, so that the I_{xy} and the I_{yz} products of inertia are zero and are not included in the simulation equations.

4.1 Translational Equations

Let the translational inertial velocity of the airplane expressed in body frame components be given by \([u,v,w]'\) and the rotational inertial velocity of the airplane in body frame components be given by \([p,q,r]'\). The equations governing translational motion can then be written as,

\[
\begin{bmatrix}
  m & 0 & 0 \\
  0 & m & 0 \\
  0 & 0 & m
\end{bmatrix}
\begin{bmatrix}
  \dot{u} \\
  \dot{v} \\
  \dot{w}
\end{bmatrix}
+ \begin{bmatrix}
  0 & -r & q \\
  r & 0 & -p \\
  -q & p & 0
\end{bmatrix}
\begin{bmatrix}
  m & 0 & 0 \\
  0 & m & 0 \\
  0 & 0 & m
\end{bmatrix}
\begin{bmatrix}
  u \\
  v \\
  w
\end{bmatrix}
= \begin{bmatrix}
  F_x_g \\
  F_y_g \\
  F_z_g
\end{bmatrix}
+ \begin{bmatrix}
  F_x_a \\
  F_y_a \\
  F_z_a
\end{bmatrix}
+ \begin{bmatrix}
  F_x_e \\
  F_y_e \\
  F_z_e
\end{bmatrix}
\]

where the subscripts "G", "A", and "E" denote gravitational, aerodynamic and thrust-induced forces. The components of the gravitational force are given by,

\[
\begin{align*}
  \begin{bmatrix}
    F_x_g \\
    F_y_g \\
    F_z_g
  \end{bmatrix} &= -m g \begin{bmatrix}
    l_{xz} \\
    l_{yx} \\
    l_{zz}
  \end{bmatrix} \\
  &= \begin{bmatrix}
    -\sin(\theta) \\
    \cos(\theta)\sin(\phi) \\
    \cos(\theta)\cos(\phi)
  \end{bmatrix}
\end{align*}
\]

4.2

where \([l_{xz} l_{yx} l_{zz}]'\) is the third column of the direction cosine matrix describing a transformation from local frame to body frame components and \(\theta\) and \(\phi\) are the Euler pitch and roll angles, respectively. The aerodynamic force components are given by,
The thrust-induced forces are defined in equations (6.8) of section 6.

### 4.2 Rotational Equations

The body frame rotational equations can be written in a form identical to equation (4.1), with the understanding that moments due to gravity are zero,

\[
\frac{d}{dt} \begin{bmatrix}
I_x & 0 & -I_{xz} \\
0 & I_y & 0 \\
-I_{xz} & 0 & I_z \\
\end{bmatrix} \begin{bmatrix}
p \\
q \\
r \\
\end{bmatrix} + \begin{bmatrix}
0 & -q & p \\
q & 0 & -p \\
-p & q & 0 \\
\end{bmatrix} \begin{bmatrix}
I_x & 0 & -I_{xz} \\
0 & I_y & 0 \\
-I_{xz} & 0 & I_z \\
\end{bmatrix} \begin{bmatrix}
p \\
q \\
r \\
\end{bmatrix}
\]

\[= \begin{bmatrix}
M_x \\
M_y \\
M_z \\
\end{bmatrix}_G + \begin{bmatrix}
M_x \\
M_y \\
M_z \\
\end{bmatrix}_A + \begin{bmatrix}
M_x \\
M_y \\
M_z \\
\end{bmatrix}_E \]  

(4.4)

and where the aerodynamic moments are given by,

\[\begin{bmatrix}
M_x \\
M_y \\
M_z \\
\end{bmatrix}_A = \overline{q} S \begin{bmatrix}
b C_l \\
\zeta C_m \\
b C_n \\
\end{bmatrix} \]  

(4.5)

The thrust-induced moments are defined in equations (6.10) of section 6.

### 4.3 Combined Accelerations

If the body frame components of translational and rotational velocity are combined into a 6x1 generalized velocity vector,

\[
\{V\} = \begin{bmatrix}
u \\
v \\
w \\
p \\
q \\
r \\
\end{bmatrix}
\]  

(4.6)

then equations (4.1) and (4.2) can be combined and written as,

\[
[M]_I \{\dot{V}\} + [\Omega][M]_I \{V\} = [F]_G + [F]_A + [F]_E
\]  

(4.7)

where the inertial mass is given by,
and the matrix representing body frame rotation is,

\[
\begin{bmatrix}
0 & -r & q & 0 & 0 & 0 \\
r & 0 & -p & 0 & 0 & 0 \\
-q & p & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -r & q & 0 \\
0 & 0 & 0 & r & 0 & -p \\
0 & 0 & 0 & -q & p & 0
\end{bmatrix}
\]

(4.9)

In order to achieve an explicit definition of the airplane accelerations, equation (4.7) must be modified. Observe that the time rate-of-change of angle of attack in still air, given by,

\[
\dot{\alpha} = \frac{uw - wu}{u^2 + w^2}
\]

(4.10)

is clearly a function of body frame accelerations. In the F/A-18 aerodynamic build-up, as is the case for almost all such aerodynamic models, the coefficients of lift and pitch contain contributions by a nondimensionalized form of the angle-of-attack rate-of-change

\[
C_X = \ldots + C_{X,\alpha} \left( \frac{\dot{\alpha} \dot{c}}{2V} \right)
\]

(4.11)

where the symbol 'X' in equation (4.11) can be replaced by 'L' (lift) or 'm' (pitch). In the F/A-18 simulation, \( C_{X,\alpha} \) is a function of Mach, altitude, and angle-of-attack. The implication of equations (4.10) and (4.11) is that the generalized aerodynamic force column vector appearing in equation (4.7) should be written as,

\[
\{ F \}_A = \left. \{ F \}_A \right|_{|V| = 0} - \{ M \}_A \{ \dot{V} \}
\]

(4.12)

where,
[M]_A represents an increment to the inertial mass matrix of equation (4.7). If we further define a generalized inertial force as,

\[ \{F\}_I = -\Omega \{M\}_I \{V\} \]  

(4.14)

and combine equations (4.7), (4.12) and (4.14), we get the equations of motion as implemented in the simulation,

\[ \dot{\{V\}} = \{F\}_I + G + A + E \]  

(4.15)

where the total mass matrix is:

\[ \{M\} = \{M\}_I + \{M\}_A \]  

(4.16)

Equation (4.15) must be solved each simulation time step for the unknown accelerations in \{V\}. Recall \{V\} = [u,v,w,p,q,r]' (equation 4.6). If the mass matrix, \{M\}, were constant, then the inverse, \{M\}^{-1}, could be formed at time zero and a simple left multiplication of the right-hand-side forces by \{M\}^{-1} would produce the accelerations. The aerodynamic part of the mass matrix, \{M\}_A, is a function of angle of attack, Mach number, altitude, and dynamic pressure and is therefore time-varying. Forming the inverse of \{M\} each time step would be prohibitive. The approach used in the simulation documented in this report is to solve (4.15) using Gaussian elimination. In a typical application of Gaussian elimination, row and column switching (pivoting) is performed to insure that the largest possible elements are used as divisors. Both partial and full pivoting strategies exist. In a general application, if the diagonal elements are used as divisors without pivoting, the divisors may become zero. For most airplanes, and for any configuration of the F/A-18, the inertial mass matrix, \{M\}_I, is sufficiently diagonally dominant and \{M\}_A is sufficiently small throughout the flight envelope, that the diagonal elements of \{M\} can be used as divisors with impunity. A custom 6x6 equation solver that employs no pivoting strategy is used in the simulation to solve (4.15). The custom solver is implemented in subroutine XRBVDC. In order to improve efficiency, the use of DO-LOOPS in XRBVDC was minimized. The simulation was tested using both the custom solver and a general purpose subroutine that employed a full pivoting strategy (the most robust form) with double precision arithmetic. The custom solver gave identical answers to 5-6 decimals and achieved a substantial reduction in total simulation run time.

An alternate approach to the solution of (4.15) is to use a series approximation to the inverse of \{M\}. This approach is valid if the time-varying part of the mass matrix is small. Thus if,

\[ \{M\} = \{M\}_I [I + \Delta M] \]  

(4.17)

then,

\[ \{M\}_I^{-1} = [I + \Delta M]^{-1} \{M\}_I^{-1} = [I - \Delta M] \{M\}_I^{-1} \]  

(4.18)
if $|\Delta M|$ is small. The inversion of $[M]$ could be done once in the initialization portion of the simulation.

### 4.4 Body Orientation Parameters

Three equivalent sets of parameters to describe the orientation of the body reference frame with respect to the the Earth frame are maintained in the simulation. The three sets are the Euler angles $(\psi, \theta, \phi)$, the quaternions $(e_0, e_1, e_2, e_3)$, and the elements of the direction cosine matrix $(l_{xx}, l_{xy}, ..., l_{zz})$. These parameters are calculated by two separate methods according to the logical switch, LEULER. If LEULER is selected, then the three sets of orientation parameters are determined by integrating the time derivatives of the Euler angles, $\dot{\psi}, \dot{\theta}, \dot{\phi}$. If LEULER is not selected, then all the orientation parameters are determined from integrating the time derivatives of the quaternions (Euler parameters). The quaternion method was implemented first and avoids the problem of a singularity that occurs in the Euler angle derivatives when the pitch angle, $\theta$, is 90°. The singularity is associated with $\theta$ because of the order of application of the Euler angle rotations in transforming from the Earth frame to the body frame, that order being heading ($\psi$), pitch ($\theta$), and roll ($\phi$). If the $\theta = 90^\circ$ region is avoided, the two methods should produce the same answer to 3-4 decimals. The Euler angle integrations were added later so the Euler angles would occur as states in the simulation and therefore linear analysis using the Euler angles as state variables could be easily performed. Time derivatives are calculated and integrated for both the Euler angles and the quaternions at all times in the simulation. The effect of LEULER is to select one set of integrated outputs and ignore the other. Equations 4.19 through 4.31 below can be found among or derived from the equations in Appendix E of Gainer and Hoffman (1972).

#### 4.4.1 Euler Angles

The time derivatives of the Euler angles are given by:

$$
\begin{align*}
\dot{\phi} &= p + \{\cos(\theta)\}^{-1} \left( \sin(\phi) \sin(\theta) q + \cos(\phi) \sin(\theta) r \right) \\
\dot{\theta} &= \cos(\phi) q - \sin(\phi) r \\
\dot{\psi} &= \{\cos(\theta)\}^{-1} \left( \sin(\phi) q + \cos(\phi) r \right)
\end{align*}
$$

(4.19)

In the simulation implementation of (4.19), the following expression is used for $\cos(\theta)$ where division by $\cos(\theta)$ is called for,

$$
C_\theta = \begin{cases} 
\frac{\theta}{|\theta|} & \text{if } |\cos(\theta)| < \varepsilon = 10^{-10} \\
\cos(\theta) & \text{otherwise}
\end{cases}
$$

(4.20)

so that division by zero when the pitch angle is at 90° is avoided. States created by integrating the derivatives are subscripted with "x" to denote the fact that they may be ignored later depending on the choice of LEULER.
\[
\psi_x = \int_0^t \psi dt + \psi_{ic}
\]
\[
\theta_x = \int_0^t \theta dt + \theta_{ic}
\]
\[
\phi_x = \int_0^t \phi dt + \phi_{ic}
\]  

(4.21)

4.4.2 Quaternions

The derivatives of the quaternions are given by:

\[
\left\{ \begin{array}{l}
\mathbf{e}_0 \\
\mathbf{e}_1 \\
\mathbf{e}_2 \\
\mathbf{e}_3
\end{array} \right\} = \left[ \begin{array}{cccc}
\mathbf{e}_0 & -\mathbf{e}_1 & -\mathbf{e}_2 & -\mathbf{e}_3 \\
\mathbf{e}_1 & \mathbf{e}_0 & -\mathbf{e}_3 & \mathbf{e}_2 \\
\mathbf{e}_2 & \mathbf{e}_3 & \mathbf{e}_0 & -\mathbf{e}_1 \\
\mathbf{e}_3 & -\mathbf{e}_2 & \mathbf{e}_1 & \mathbf{e}_0
\end{array} \right] \left\{ \begin{array}{l}
p \\
q \\
r
\end{array} \right\}
\]

(4.22)

Define

\[
\mathbf{e} = \mathbf{e}_0 + \mathbf{i}\mathbf{e}_1 + \mathbf{j}\mathbf{e}_2 + \mathbf{k}\mathbf{e}_3 = \left\{ \begin{array}{l}
\mathbf{e}_0 \\
\mathbf{e}_1 \\
\mathbf{e}_2 \\
\mathbf{e}_3
\end{array} \right\} \quad \text{and} \quad \mathbf{w} = \mathbf{i}p + \mathbf{j}q + \mathbf{k}r = \left\{ \begin{array}{l}
p \\
q \\
r
\end{array} \right\}
\]

where the following rules of multiplication govern the \( \mathbf{i}, \mathbf{j}, \mathbf{k} \) basis vectors.

\[
\mathbf{i}\mathbf{j} = -\mathbf{j}\mathbf{i} = \mathbf{k}, \quad \mathbf{j}\mathbf{k} = -\mathbf{k}\mathbf{j} = \mathbf{i}, \quad \mathbf{k}\mathbf{i} = -\mathbf{i}\mathbf{k} = \mathbf{j}, \quad \text{and} \quad \mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -1.
\]

Note that the complex conjugate of \( \mathbf{e} \), the quaternion vector, is given by \( \overline{\mathbf{e}} = \mathbf{e}_0 - \mathbf{i}\mathbf{e}_1 - \mathbf{j}\mathbf{e}_2 - \mathbf{k}\mathbf{e}_3 \).

Observing that the product \( \mathbf{e}\mathbf{w} \) is given by,

\[
\mathbf{e}\mathbf{w} = -p\mathbf{e}_1 - q\mathbf{e}_2 - r\mathbf{e}_3 + i[p\mathbf{e}_0 - q\mathbf{e}_3 + r\mathbf{e}_2] + j[p\mathbf{e}_3 + q\mathbf{e}_0 - r\mathbf{e}_1] + k[-p\mathbf{e}_2 + q\mathbf{e}_1 + r\mathbf{e}_0]
\]  

(4.23)

Equation (4.22) can be rewritten as,

\[
\dot{\mathbf{e}} = \mathbf{e}\mathbf{w} \quad \text{or} \quad \overline{\dot{\mathbf{e}}} = \overline{\mathbf{e}}\overline{\mathbf{w}} \quad \text{where} \quad \mathbf{e} = \left\{ \begin{array}{l}
\mathbf{e}_0 \\
\mathbf{e}_1 \\
\mathbf{e}_2 \\
\mathbf{e}_3
\end{array} \right\}, \quad \overline{\mathbf{e}} = \left\{ \begin{array}{l}
\mathbf{e}_0 \\
-\mathbf{e}_1 \\
-\mathbf{e}_2 \\
-\mathbf{e}_3
\end{array} \right\}
\]

(4.24)
where left multiplication by \( e \) is equivalent to left multiplication by the 4x4 matrix of equation 4.22. The components of the quaternion rate, \( \dot{e} \), are then integrated to produce quaternion states.

\[
e_{j0x} = \int_{0}^{t} \dot{e}_{j} \, dt + e_{j1c} \quad (j = 0,3) \quad (4.25)
\]

The quaternions are used as the generating set from which the other two equivalent set of orientation parameters are derived. The quaternions in their unnormalized form are calculated according to the value of LEULER. The additional zero subscript on the quaternions serves to indicate their unnormalized status.

\[
e_{00} = \begin{cases} 
\cos(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) + \sin(\frac{\psi_{x}}{2})\sin(\frac{\theta_{x}}{2})\sin(\frac{\phi_{x}}{2}) & \text{LEULER=T.} \\
\cos(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) & \text{LEULER=F.}
\end{cases}
\]

\[
e_{10} = \begin{cases} 
\cos(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\sin(\frac{\phi_{x}}{2}) + \sin(\frac{\psi_{x}}{2})\sin(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) & \text{LEULER=T.} \\
\cos(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\sin(\frac{\phi_{x}}{2}) & \text{LEULER=F.}
\end{cases}
\]

\[
e_{20} = \begin{cases} 
\cos(\frac{\psi_{x}}{2})\sin(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) + \sin(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\sin(\frac{\phi_{x}}{2}) & \text{LEULER=T.} \\
\cos(\frac{\psi_{x}}{2})\sin(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) & \text{LEULER=F.}
\end{cases}
\]

\[
e_{30} = \begin{cases} 
\sin(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) + \cos(\frac{\psi_{x}}{2})\sin(\frac{\theta_{x}}{2})\sin(\frac{\phi_{x}}{2}) & \text{LEULER=T.} \\
\sin(\frac{\psi_{x}}{2})\cos(\frac{\theta_{x}}{2})\cos(\frac{\phi_{x}}{2}) & \text{LEULER=F.}
\end{cases}
\]

The quaternions are then normalized. Note that if \( \psi, \theta, \phi \) are small, then to first order, \( \psi = e_3, \theta = e_2, \phi = e_1 \), and \( e_0 = 1 \). The norm of the quaternion vector is formed,

\[
|e| = \left\{ e_{00}^2 + e_{10}^2 + e_{20}^2 + e_{30}^2 \right\}^{1/2}
\]

and then used to scale the quaternion components:

\[
e_j = e_{j0} / |e| \quad (j=0,3)
\]

and
While not required for the following development, it is interesting to observe that:

\[
\begin{pmatrix}
|e| e_1 \\
0 \\
0 \\
0
\end{pmatrix} = e e
\]  

(4.29)

4.4.3 Direction Cosine Matrix

The direction cosine matrix elements and the final Euler angle can then be derived from the normalized quaternions:

\[
\begin{pmatrix}
0 \\
l_{xx} \\
l_{yx} \\
l_{zx}
\end{pmatrix} = \bar{e} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} e
\]

(4.30)

where in expanded form, the first equation of (4.30) is given by,

\[
\begin{pmatrix}
0 \\
l_{xx} \\
l_{yx} \\
l_{zx}
\end{pmatrix} = \bar{e} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} e
\]

(4.31)

Finally, the Euler angles can be calculated directly from the elements of the direction cosine matrix.

\[
\begin{align*}
\psi &= \tan^{-1} \left\{ \frac{l_{yy}}{l_{xx}} \right\} \\
\theta &= \sin^{-1} \left\{ \frac{l_{xz}}{} \right\} \\
\phi &= \tan^{-1} \left\{ \frac{l_{yz}}{l_{zz}} \right\}
\end{align*}
\]

(4.32)
5. AERODYNAMIC MODEL

5.1 Aerodynamic Data Sources

The aerodynamic characteristics of the F/A-18 are discussed in detail in MDC A7247, vol. 1,2. The low-speed report, (MDC A7247, vol. 1), describes the force and moment build-up for three basic configurations (maneuvering, catapult and approach) in the angle-of-attack range of -10° to +40°. The maneuvering configuration is described in section 3 of MDC A7247, vol 1, while the low-speed/high lift configurations (approach and catapult) are described in section 4 of MDC A7247, vol 1. MDC A7247, vol. 2 describes the force and moment build-up for the maneuvering configuration in the angle-of-attack range of +40° to +90°. In the MDC batch simulation code (discussed in section 1.2 of this report) four separate force and moment build-ups; "clean", "power approach", "take-off", and "high" are implemented. The first three configurations of the MDC batch simulation code, ("clean", "power approach", and "take-off"), correspond to the three configurations of MDC A7247, vol. 1, ("maneuvering", "approach", and "catapult"). The fourth build-up in the MDC batch simulation code corresponds to the high-angle-of-attack, maneuvering configuration of MDC A7247, vol. 2. The "maneuvering" configuration equations of MDC A7247, vol. 1 and the "clean" configuration equations of the MDC batch simulation code are slightly different. The MDC A7247, vol 1 "maneuvering" build-up has increments due to stores while the MDC batch simulation code "clean" build-up has increments due to gear deployment. The simulation aerodynamic model described in this report is a combination of the maneuvering configurations described in MDC A7247, vol. 1,2 and in the MDC batch simulation code with a few small extensions extracted from the high-lift configurations. In addition, MDC report A8575 contains background material, including a history of configuration development, a history of the substantiating wind-tunnel testing, and propulsion system characteristics.

As required by the simulation equations of motion discussed in section 4 of this report, the total aerodynamic force and moment coefficients are calculated in two parts. The portion of the total coefficient that is an explicit function of airplane velocities or control surface positions, the steady flow part, is calculated in subroutine SFAERRF. The part of the total coefficient that is proportional to airplane acceleration, the unsteady part, is calculated in subroutine USAERRF. The steady flow result is the sum of the static components plus the effect of body angular rates. The unsteady part includes the effect of the time rate of change of angle of attack or sideslip.

The moment coefficients and input velocities are defined about the aerodynamic reference center, (a.r.c.), which is defined in Table 5.1.

<table>
<thead>
<tr>
<th>Table 5.1. Aerodynamic Reference Center Coordinates</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fuselage Station (FS), in. 458.56 (+ aft)</td>
</tr>
<tr>
<td>Buttock Line (BL), in. 0.00 (+ right)</td>
</tr>
<tr>
<td>Water Line (WL), in. 100.00 (+ up)</td>
</tr>
</tbody>
</table>

The (FS/BL/WL) coordinates define a body-fixed axes system. The body axes system used in the equations of motion is centered at the center of gravity, aligned with the (FS/BL/WL) system, but has the sign convention of +x forward, + y out the right wing, and +z down (figure 3-1).

There are two logical variables that affect the coefficient calculations in the simulation described in this report, LQSE and LRTE. If the quasi-static-elastic logical, (LQSE), is true, then all the flex/rigid increments and effectiveness factors that were in the original model remain in effect. If LQSE is
false, then all the flex/rigid coefficients are set to the values they approach as air density, and therefore deformation, goes to zero. Setting LQSE false causes the aerodynamic forces and moments appropriate to the wind-tunnel-shape, which is not necessarily the jig-shape, of the airplane to be calculated. The LQSE option allows the use of the same code in a simulation where the flexible modes are actively modeled. The second logical is the real-time-equivalent flag (LRTE). If LRTE is true, then various differences that exist between the aerodynamic model used in the LaRC real-time simulation (dmsfl8) and the ACSL simulation described in this report are removed. These differences are discussed in section 5.5.2 "(Leading-Edge Flap Effects (Y,l,n))", section 5.5.5 ("Rudder Effects"), and section 5.5.9 ("Effect of Airplane Asymmetries (Y,l,n)") of this report.

The difference between the two aerodynamic models arises from changes made to the fl8bas simulation math model that were not duplicated in the LaRC real-time simulation. The first of these changes was the inclusion of a rolling moment increment, $\Delta C_{lasm}$, that is a function only of angle of attack, $\alpha$, and nonzero for $\alpha > 40^\circ$. The effect is to introduce a rolling disturbance as the simulated airplane moves through the 40° to 60° angle-of-attack region. The term arises from nose asymmetries and is discussed on pages 4-20,21 of MDC A7247, vol. 2 and section 5.5.9 ("Effect of Airplane Asymmetries (Y,l,n)") of this report. The dmsfl8 simulation has the term $\Delta C_{lasm}$ zeroed out. The second change is the inclusion of a nonzero estimate for $C_{L_{asm}}$ (lift coefficient per unit leading-edge flap) for the case of $40^\circ < \alpha \leq 45^\circ$ and leading-edge flap position different from the scheduled value. This change is discussed in section 5.3.4 ("Leading-Edge Flap Effects") of this report. The third difference is the inclusion of rudder toe-in effects on drag, pitch, and lift in the ACSL simulation. Rudder toe-in can induce significant pitch moment and is an appropriate effect to include in a simulation supporting agility research. Symmetric rudder effects on pitch are discussed in section 5.3.9 ("Rudder Effects") of this report.

In the reconstruction equations, the total aerodynamic force and moment coefficients are built up from a large collection of intermediate coefficients. An attempt has been made to adopt symbolic conventions that indicate the source and purpose of the intermediate coefficients. Typically, the total force or moment coefficient consists of a "basic quantity" plus additional coefficients. The "basic contribution" is denoted by a zero subscript and is a function of Mach and either angle of attack or sideslip. For the "basic contribution", the controls are at a nominal position (typically zero) and the airplane is undeformed. Additional coefficients that represent increments to another coefficient (basic or otherwise) will begin with 'A'. Increments due to 'x' are the result of evaluating a tabular function where 'x' was an input. Coefficients that resemble classic stability derivatives and are to be multiplied by the appropriate control or nondimensional quantity will have no 'A' symbol.

5.2 Control Surface Sign Conventions

The control surface sign convention used in the aerodynamic model follows the convention established in MDC A7247, vol. 1. The terms "stabilator" and "horizontal tail" are used interchangeably in various MDC documents. MDC stability and control reports that describe the aerodynamic model (MDC A7247, vol. 1,2), tend to use the term "horizontal tail". MDC reports describing the flight control laws (MDC A4107, vol. 1 and MDC A7813, vol. 1,2,3), use "stabilator". "Stabilator" will be used in this document. In addition, the symbols $\delta_H$ and $\delta_{HT}$ are used interchangeably in MDC A7247, vol. 1 to refer to "horizontal tail" deflection.
Table 5.2. Control Deflection Sign Conventions

</tbody>
</table>

5.3 Lift and Pitch (L, m)

The reconstruction equations that are used to compute the total lift and pitch coefficients are almost identical and are combined in a common form in equation (5.1). To the basic lift and pitch reconstruction equations (MDC A7247, vol. 1, section 3.1.1) the following have been added; (1) landing gear effects from the MDC batch simulation code (lines 805-906 of subroutine ARO18CN), and (2), rudder toe-in effects extracted from section 4.1.10 of MDC A7247, vol. 1. Replacing "X" in the equation below with "L" or "m" as appropriate will give the lift and pitch equations, respectively. The total lift/pitch coefficient is given by,

\[
C_X = C_{Xsf} + C_{X\alpha} \left( \frac{\alpha \delta}{2V} \right)
\]

(5.1)

where the steady flow lift/pitch coefficient is given by,
\[ C_{X_{sf}} = C_{X_0} + \Delta C_{X_0}^F + \frac{1}{2} R_{C_X}^F \left[ \Delta C_{X_0} \delta_{HL} + \Delta C_{X_0} \delta_{HR} \right] \]

\[ + R_{C_L} \delta_A \left[ \Delta C_{X_0} \delta_{AL} + \Delta C_{X_0} \delta_{AR} \right] \]

\[ + C_{X_0} \delta_n + \Delta C_{X_0} \delta_n + \left[ C_{X_0} \delta_f + \Delta C_{X_0} \delta_f \right] \delta_f \]

\[ + \Delta C_{X_0} \delta_{SB} + \Delta C_{X_0} \delta_{LG} + \Delta C_{X_0} \delta_{LR} + \Delta C_{X_0} \delta_{RT} \]

\[ + \Delta C_{X_0} \delta_{stores} + \left[ C_{X_0} + \Delta C_{X_0} \right] \frac{q^e}{2V} \]  

(5.2)

while the unsteady component of lift/pitch, i.e., proportional to nondimensional rate of change of angle of attack is given by,

\[ C_{X_0} = C_{X_0} + \Delta C_{X_0} \]  

(5.3)

The individual components of the lift and pitch reconstruction equations, (5.2, 5.3), are defined in sections (5.3.1) through (5.3.11). These components are for the most part calculated by performing linear interpolations according to tabulated functions. The variables used as input to the interpolation functions are normally limited to prevent extrapolation. Thus once the actual state or control variable reaches the limit of the data, no further change occurs in the coefficient. The input variables and the limits (if applied) are shown for each function look-up.

5.3.1 Basic Airframe Coefficient (L,m)

The basic airframe lift/pitch coefficient for the rigid airplane with control surfaces undeflected is given by,

\[ C_{X_0} = \begin{cases} 
F_{C_X O}(\alpha|^{40}_{1.2}, M|^{2.2}) & \alpha \leq 40^\circ; \delta_n = 0^\circ \\
F_{H C_X O}(\alpha|^{40}_{4.0}, M|^{1.1}) & \alpha > 40^\circ; \delta_n = 34^\circ 
\end{cases} \]  

(5.4)

where the notation is defined as follows,

\[ F_{C_X O}(\alpha|^{40}_{1.2}, M|^{2.2}) \triangleq \left\{ \begin{array}{l}
\text{the function } F_{C_X O} \text{ as defined by data tables} \\
\text{is evaluated at an angle of attack and Mach number} \\
\text{that are limited according to the brackets.}
\end{array} \right\} \]

At low angle of attack (\( \alpha \leq 40^\circ \)), \( C_{X_0} \) refers to a zero stabilator, retracted flaps configuration. At high angle of attack (\( \alpha > 40^\circ \)), basic lift/pitch, \( C_{X_0} \), refers to a configuration with zero stabilator.
and a leading-edge flap deflection of 34°. The elastic increment to the basic airframe lift/pitch coefficient is:

\[
\Delta C_{x_0}^F = \begin{cases} 
\left( \frac{M - 2}{0.4} \right) \left[ 1 + F_{DCXOF} \left( \alpha^{[32]} \cdot H_p^{[60000]} \right) \right] & \text{LQSE} = \text{T.} \\
0.0 & \text{LQSE} = \text{F.}
\end{cases}
\]

(5.5)

In figures 3.1.1-1 through 3.1.1-22 of MDC A7247, vol. 1, the coefficients \(C_{x_0}\) and \(\Delta C_{x_0}^F\) are defined and combined for presentation into one coefficient.

### 5.3.2 Stabilator Effects (L,m)

Increments due to left and right stabilator (horizontal tail) deflections are,

\[
\Delta C_{x_0}^{\delta_{HL,R}} = \begin{cases} 
F_{DCXDH} \left( \alpha^{[40]} \cdot \delta_{HL,R}^{[10.5]} \cdot M^{[2]} \right) & \alpha \leq 40 \\
F_{HDCXDH} \left( \alpha^{[90]} \cdot \delta_{HL,R}^{[10.5]} \cdot M^{[1.1]} \right) & \alpha > 40
\end{cases}
\]

(5.6)

The elastic/rigid stabilator effectiveness factor is,

\[
R_{C_{x_0}^{\delta_H}}^F = \begin{cases} 
F_{FRCXDH} \left( \alpha^{[2]} \cdot H_p^{[60000]} \right) & \text{LQSE} = \text{T.} \\
1.0 & \text{LQSE} = \text{F.}
\end{cases}
\]

(5.7)

### 5.3.3 Aileron Effects (L,m)

The lift/pitch increments due to left and right aileron deflections are,

\[
\Delta C_{x_0}^{\delta_{A,L,R}} = \begin{cases} 
F_{DCXDA} \left( \alpha^{[40]} \cdot \delta_{A,L/R}^{[25]} \cdot M^{[2]} \right) & \alpha \leq 40 \degree \\
F_{HDCXDA} \left( \alpha^{[90]} \cdot \delta_{A,L/R}^{[25]} \cdot M^{[1.2]} \right) & \alpha > 40 \degree
\end{cases}
\]

(5.8)

The elastic/rigid aileron effectiveness factor has been replaced by a flight-test derived quantity, a "flight/rigid" factor. This factor is larger than unity in the "rigid" limit because it reflects the configuration change that occurred between 1979 and 1984 in which the aileron span was increased outboard to the wingtip, (MDC A8575, page 1-4). The data in \(F_{DCXDA}\) and \(F_{HDCXDA}\) are for the small aileron (MDC A7247, vol. 1, page 3-357). Note that \(R_{C_{L_\delta A}^{\text{FLT}}}\) is used in both the lift (\(C_{L_{\text{sf}}}\)) and pitch (\(C_{m_{\text{sf}}}\)) equations.

\[
R_{C_{L_\delta A}^{\text{FLT}}} = \begin{cases} 
F_{FFCLDA} \left( \alpha^{[2]} \cdot H_p^{[60000]} \right) & \text{LQSE} = \text{T.} \\
1.25 & \text{LQSE} = \text{F.}
\end{cases}
\]

(5.9)
5.3.4 Leading-Edge Flap Effects \((L,m)\)

The assumption in MDC A7247, vol. 1,2 and the MDC batch simulation code is that the leading-edge flaps are commanded according to the maneuvering flap schedule and will remain fixed at 34° if angle of attack is above 40°. If angle of attack is above 40°, \(C_{Xo}\), defined in equation (5.4), includes the effect of the nonzero leading-edge flaps. Accordingly, \(C_{X\delta_n}\), the lift/pitch per degree of leading-edge flap, is not defined in MDC A7247, vol. 2 and is set to zero in the MDC batch simulation code if \(\alpha > 40°\). As a result, when the simulated airplane transitions from the low angle-of-attack database (\(\alpha \leq 40°\)) to the high angle-of-attack database (\(\alpha > 40°\)), a potential discontinuity can arise. If the leading-edge flaps are at 34° when the simulation goes through \(\alpha=40°\), no discontinuity in \(C_{Xo}\) occurs. However, if the leading-edge flaps are not on schedule, then a discontinuity in \(C_{Xo}\) exists. To remove this potential discontinuity in the \(fl8bas\) simulation, \(C_{X\delta_n}\) is not set to zero abruptly at \(\alpha=40°\), but rather is ramped to zero as angle of attack goes from 40° to 45°. Furthermore, when angle-of-attack is above 40°, \(C_{X\delta_n}\) is multiplied by the difference between leading-edge flaps and 34°, the position at which the high angle-of-attack \(C_{Xo}\) data was taken, instead of the total \(\delta_n\). Thus,

\[
C_{X\delta_n} = \begin{cases} 
F_{CXDN}(\alpha|40°,M|^{1.2}) & \alpha \leq 40 \\
\left(\frac{45 - \alpha}{5}\right)^{1/0} F_{CXDN}(\alpha=40°,M|^{1.2}) & \alpha > 40; \text{LRTE=.T.} \\
0.0 & \alpha > 40; \text{LRTE=.F.}
\end{cases}
\]  

(5.10)

where

\[
\delta_{n1} = \begin{cases} 
\delta_n & \alpha \leq 40 \\
\delta_n - 34 & \alpha > 40
\end{cases}
\]

(5.11)

The elastic increments to the leading-edge flap sensitivity for lift and pitch are,

\[
\Delta C_{L\delta_n} = \begin{cases} 
(M - 0.6)^{1/0} F_{DCLDNF}(\alpha|4^{32},M|^{1.1},H_\rho|^{60000}) & \text{LQSE=.T.} \\
0.0 & \text{LQSE=.F.}
\end{cases}
\]

(5.12)

and

\[
\Delta C_{m\delta_n} = \begin{cases} 
(M - 0.4)^{1/0} F_{DCMDNF}(\alpha|4^{32},M|^{1.1},H_\rho|^{60000}) & \text{LQSE=.T.} \\
0.0 & \text{LQSE=.F.}
\end{cases}
\]

(5.13)
The factor \( \left( \frac{M - 0.6}{0.2} \right)_0 \) serves to ramp in the full value of \( \Delta C_{L,\delta_n}^F \) as Mach goes from 0.6 to 0.8.

Similarly, \( \left( \frac{M - 0.2}{0.4} \right)_0 \) ramps in the full value of \( \Delta C_{m,\delta_n}^F \) by going from zero to one as Mach goes from 0.2 to 0.6.

5.3.5 *Trailing-Edge Flap Effects* \((L,m)\)

The lift/pitch per degree deflection of symmetric trailing-edge flaps is,

\[
C_{X\delta_f} = \begin{cases} 
F_{CXDF}(\alpha^{[40, M^{[1.1]}_2}) & \alpha \leq 40^0 \\
0.0 & \alpha > 40^0 
\end{cases}
\]  

The elastic increment to the trailing-edge flap sensitivity is,

\[
\Delta C_{X\delta_f}^F = \begin{cases} 
\left( \frac{M - 0.2}{0.4} \right)_0 F_{DCXDF}(\alpha^{[32, M^{[1.6]}_6}, H_p^{[60000]} \leq 40; \text{LQSE=T} \\
0.0 & \text{otherwise}
\end{cases}
\]

5.3.6 *Speed Brake Effects* \((L,m)\)

The increments due to speed brake deflection are slightly different for lift and pitch. The lift increment is to be multiplied by normalized speed brake deflection, \( \frac{\delta_{SB}}{60} \). For the low angle-of-attack case, the pitch increment is itself a function of speed brake and no multiplier is needed.

\[
\Delta C_{LSB} = \begin{cases} 
\left( \frac{\delta_{SB}}{60} \right) F_{DCLS}(\alpha^{[40, M^{[1.2]}_2}) & \alpha \leq 40^0 \\
\left( \frac{\delta_{SB}}{60} \right) F_{HDCLS}(\alpha^{[90, M^{[1.2]}_2}) & \alpha > 40^0 
\end{cases}
\]  

\[
\Delta C_{mSB} = \begin{cases} 
F_{DCMSB}(\alpha^{[40, M^{[1.6]}_2}, \delta_{SB}^{[60]} \leq 40^0 \\
\left( \frac{\delta_{SB}}{60} \right) F_{HDCMSB}(\alpha^{[90, M^{[1.2]}_2}) & \alpha > 40^0 
\end{cases}
\]
5.3.7 Stores \((L,m)\)

The increment due to stores is discussed in MDC A7247, vol. 1, section 3.1.8, for the cases of Escort, Escort Overload, and Interdiction mission loadings. The quantity is currently set to zero in the \(fl8bas\) simulation described in this report.

\[
\Delta C_{X_{\text{stores}}} = 0.0
\]  \(5.18\)

5.3.8 Landing Gear Effects \((L,m)\)

Increments to lift, pitch, and drag due to landing gear deployment are discussed on pages 4-75 and 4-76 of reference MDC A7247, vol. 1. In MDC A7247, vol. 1, landing gear increments are included only for the high-lift (take-off and approach) configurations. In the MDC batch simulation, landing gear increments are included in the lift, pitch, and drag build-up for the maneuvering ("clean") configuration. The increments used in the MDC batch simulation for the maneuvering configuration are different than those shown on 4-76 of MDC A7247, vol. 1. The increments used in the \(fl8bas\) simulation described in this report are those of MDC batch simulation. These increments are to be multiplied by normalized landing gear deployment. While studies to date have had no requirement for the aerodynamic effects of the landing gear being included, there is virtually no extra computational cost as the code calculating the coefficients is bypassed if the gear is retracted.

\[
\Delta C_{X_{\text{LG}}} = \begin{cases} 
F_{CXLG} \left( \alpha \right) & \alpha \leq 40^\circ \\
0.0 & \alpha > 40^\circ
\end{cases}
\]  \(5.19\)

5.3.9 Rudder Effects \((L,m)\)

The increment to lift due to antisymmetric rudder is included in the high lift configurations described in section 4.1.10 of MDC A7247, vol. 1, but not in the maneuvering configuration. The lift increment is set to zero in the \(fl8bas\) simulation described in this report. A nonzero pitch increment is included in the \(fl8bas\) simulation,

\[
\Delta C_{L_{\delta R}} = 0.0
\]  \(5.20\)

\[
\Delta C_{m_{\delta R}} = \begin{cases} 
F_{DCMDR} \left( \alpha \right) & \alpha \leq 40^\circ \\
F_{HDCMDR} \left( \alpha \right) & \alpha > 40^\circ
\end{cases}
\]  \(5.21\)

Symmetric rudder is used in approach and landing, but is not part of the nominal maneuvering configuration model. While the pitch channel of the flight control system makes no use of symmetric rudder in the auto-flap-up (AFU), maneuvering mode, future agility-oriented research control laws may employ such a command. Therefore, increments in lift/pitch due to symmetric rudder (toe-in) have been added to the maneuvering configuration by using the increment developed for the high-lift configurations and discussed in section 4.1.10 of MDC A7247, vol. 1. The increments due to symmetric rudder for the \(fl8bas\) simulation are,
Since the rudder toe-in coefficient was developed for the low speed/high lift configurations, there is no associated flex/rigid increment or effectiveness factor (page 4-5 of MDC A7247, vol. 1).

5.3.10 Pitch Rate \((L,m)\)

The pitch rate derivative for lift/pitch is,

\[
C_{\chi q} = \begin{cases} 
F_{\text{DCXQ}} (\alpha^40, M_{2.2}) & \alpha \leq 40^\circ \\
F_{\text{HCXQ}} (\alpha_{40}, M_{1.1}) & \alpha > 40^\circ 
\end{cases} \quad (5.23)
\]

The elastic increment to the pitch derivative for lift/pitch is,

\[
\Delta C_{\chi q}^F = \begin{cases} 
F_{\text{DCXQF}} (M_{2.2}, H\rho_0^{60000}) & \text{LQSE=.T.} \\
0.0 & \text{LQSE=.F.} 
\end{cases} \quad (5.24)
\]

5.3.11 Angle-of-Attack Rate \((L,m)\)

The angle-of-attack rate derivative for lift/pitch for the rigid airplane is,

\[
C_{\chi \dot{\alpha}} = \begin{cases} 
F_{\text{CXAD}} (\alpha^40, M_{2.2}) & \alpha \leq 40^\circ \\
F_{\text{HCXAD}} (\alpha_{40}, M_{1.1}) & \alpha > 40^\circ 
\end{cases} \quad (5.24)
\]

while the elastic increment to the angle-of-attack rate derivative for lift/pitch is,

\[
\Delta C_{\chi \dot{\alpha}}^F = \begin{cases} 
\left(1 - \frac{\alpha}{3}\right)^4_0 F_{\text{DCXADF}} (M_{2.2}, H\rho_0^{60000}) & \text{LQSE=.T.} \\
0.0 & \text{LQSE=.F.} 
\end{cases} \quad (5.25)
\]
5.4 Drag

Drag is not discussed in MDC A7247, vol. 1 for the maneuvering configuration. The total drag coefficient equation is taken from the MDC batch simulation and is repeated below,

\[
C_{Dsf} = C_{D0} + \Delta C_{DCL} + \frac{1}{2} \left[ \Delta C_{D\delta H_L} + \Delta C_{D\delta H_R} \right] + C_{D\delta n} \delta n_1 + C_{D\delta f} \delta f \\
+ \Delta C_{D\delta SB} + \Delta C_{D\delta LG} \delta s_L + \Delta C_{D\delta RT}
\] (5.26)

5.4.1 Basic Drag Coefficient

The basic drag coefficient is given by,

\[
C_{D0} = \begin{cases} 
F_{CDO} (\alpha|_{40^\circ}, |_{12^0}, M_{1.2}^2) & \alpha \leq 40^\circ \\
F_{HCDO} (\alpha|_{90^\circ}, |_{40^\circ}, M_{1.2}^1) & \alpha > 40^\circ
\end{cases}
\] (5.27)

When in the low-angle-of-attack regime, an additional drag increment due to lift is calculated. However, \( C_{D0} \) does not represent zero-lift drag. \( C_{D0} \) has the characteristic parabolic shape of the standard drag polar and already includes the basic effects of lift on drag. An additional drag increment due to lift is defined in the MDC batch simulation as

\[
\Delta C_{DCL} = \begin{cases} 
F_{DCDCL} (\alpha|_{40^\circ}, |_{12^0}, M_{1.2}^2) & \alpha \leq 40^\circ \\
0.0 & \alpha > 40^\circ
\end{cases}
\] (5.28)

\( \Delta C_{DCL} \) represents small corrections to \( C_{D0} \) and can be positive or negative. In the MDC batch simulation comments, \( \Delta C_{DCL} \) is described as a correction "from tunnel drag to full-scale" and is presumably the result of flight data. Due to the explicit formulation of the equations of motion (section 4.3 of this document), \( C_L \) is not readily available in the fl18bas simulation. Therefore, in the fl18bas simulation implementation of (5.28), \( \Delta C_{DCL} \) is a function of \( C_{Lsf} \) instead of \( C_L \). The difference in aircraft response induced by using \( C_{Lsf} \) instead of \( C_L \) in equation (5.28) is negligible.

5.4.2 Stabilator Drag Increment

The drag increments due to left and right stabilator (horizontal tail) deflection are given by:

\[
\Delta C_{D\delta H_{L,R}} = \begin{cases} 
F_{DCDHH} (\alpha|_{40^\circ}, |_{12^0}, \delta_{H_{L,R}}|_{10.5}, M_{1.2}^1) & \alpha \leq 40^\circ \\
F_{HDCDHH} (\alpha|_{90^\circ}, |_{40^\circ}, \delta_{H_{L,R}}|_{10.5}, M_{1.2}^1) & \alpha > 40^\circ
\end{cases}
\] (5.29)
5.4.3 Leading-Edge Flap Drag Derivative

The drag per degree of symmetric leading-edge flap is:

\[ C_{D\delta_n} = \begin{cases} 
F_{CDDN} (\alpha |_{40}, M |_{1.2} ) & \alpha \leq 40^\circ \\
\left(\frac{45-\alpha}{5}\right)^{1/0} F_{CXXDN} (\alpha=40, M |_{1.2} ) & \alpha > 40^\circ 
\end{cases} \quad (5.30) \]

5.4.4 Trailing-Edge Flap Drag Derivative

The drag per degree of symmetric trailing-edge flap is,

\[ C_{D\delta_f} = \begin{cases} 
F_{CDDF} (\alpha |_{40}, M |_{1.1} ) & \alpha \leq 40^\circ \\
0.0 & \alpha > 40^\circ 
\end{cases} \quad (5.31) \]

5.4.5 Speed Brake Drag Derivative

The drag increment due to full speed brake deflection is,

\[ \Delta C_{DSB} = \begin{cases} 
\left(\frac{\delta_{SB}}{60}\right) F_{DCDSB} (\alpha |_{40}, M |_{1.2} ) & \alpha \leq 40^\circ \\
\left(\frac{\delta_{SB}}{60}\right) F_{HDCDSB} (\alpha |_{90}, M |_{1.2} ) & \alpha > 40^\circ 
\end{cases} \quad (5.32) \]

5.4.6 Landing Gear Drag Increment

The drag increment due to full landing gear deployment is,

\[ \Delta C_{DLG} = \begin{cases} 
F_{DCDLG} (\alpha |_{30}) & \alpha \leq 40^\circ \\
0.0 & \alpha > 40^\circ 
\end{cases} \quad (5.33) \]

5.4.7 Rudder Drag Increment

As discussed in the lift/pitch term build-up, a drag increment due to symmetric rudder (toe-in) has been added to the maneuvering configuration by using the increment developed for the high-lift configurations and discussed in section 4.1.10 of MDC A7247, vol. 1. Recall that the low speed/high lift configurations are considered low-angle-of-attack configurations. As discussed in section 4.1.2.9, no elastic/rigid adjustments are defined for the rudder toe-in coefficients in MDC A7247, vol. 1.
\[
\Delta C_{DRT} = \begin{cases} 
F_{\text{CDDRT}}(\alpha|^{40}_{-10}, \delta_{RT}^{30}_{-15}, \delta_{f/A}^{45}_{0}) & \alpha \leq 40^\circ \\
0.0 & \alpha > 40^\circ 
\end{cases} 
\]  \hspace{1cm} (5.33)

5.5 Side-Force, Roll, Yaw (Y,l,n)

As in the case of lift/pitch, the same reconstruction equation can be used for side force, roll and yaw. The appropriate equation is recovered by substituting "Y" (side force), "l" (roll), or "n" (yaw) for "x" in equation (5.34) below.

\[
C_{X_{sf}} = C_{X_0} + \Delta C_{X_{sf}}^F \beta + \Delta C_{X_{f}}^F \left(\frac{\delta_{n}}{25}\right) + \Delta C_{X_{\delta}}^F \left(\frac{\delta_{f}}{20}\right) + C_{X_{\delta}} \Delta \delta_{n} \nonumber
\]

\[
+ C_{X_{\delta}} \Delta \delta_{f} + R_{C_{X_{\delta}}}^F \left[\Delta C_{X_{\delta}}^F + \Delta C_{X_{\delta}}^A \right] \nonumber
\]

\[
+ \Delta C_{X_{\delta}}^R R_{C_{X_{\delta}}} R_{C_{X_{\delta}}}^F + R_{C_{X_{\delta}}}^F C_{X_{\delta}} \Delta \delta_{H} + \beta \Delta C_{X_{\delta}}^S \nonumber
\]

\[
+ \Delta C_{X_{asm}} + C_{X_{p}} R_{C_{X_{p}}}^F \left(\frac{p^2}{2V}\right) + \left(C_{X_{r}} + \Delta C_{X_{r}}^F \right) \left(\frac{r^2}{2V}\right) \hspace{1cm} (5.34)
\]

5.5.1 Basic Airframe Coefficient (Y,l,n)

The basic airframe coefficient for the rigid airplane with controls at zero is given by,

\[
C_{X_0} = \begin{cases} 
k C_{X_{o1}} + (1-k) C_{X_{o2}} & \alpha \leq 40^\circ \\
F_{HCXO} (\beta, \alpha|_{40}^{90}, M|_{.2}^{.1}) & \alpha > 40^\circ 
\end{cases} \hspace{1cm} (5.35)
\]

where,

\[
C_{X_{o1}} = F_{C XO1} (\beta, \alpha|_{40}^{90}, M|_{.2}^{.1}) \hspace{1cm} (5.36.a)
\]

\[
C_{X_{o2}} = F_{C XO2} (\beta, \alpha|_{20}^{90}, M|_{1}^{.2}) \hspace{1cm} (5.36.b)
\]

\[
\text{and } k = \frac{M|_{1}}{.1} |_{0}^{1} \hspace{1cm} (5.36.c)
\]

5.5.2 Leading-Edge Flap Effects (Y,l,n)

If sideslip is nonzero, then symmetric leading-edge flap deployment produces a change in the lateral/directional coefficients. The increment due to full 25 degree deployment of symmetric leading-edge flaps in the presence of nonzero sideslip is given by,
\[
\Delta C_{X\delta_n} = \begin{cases} 
\frac{\beta}{|\beta|} F_{DCXDN} \left( |\beta|^{20}, \alpha|^{40}, M|^{1.1} \right) & |\alpha| \leq 40^\circ \\
0.0 & \alpha > 40^\circ
\end{cases}
\] (5.37)

where $\Delta C_{X\delta_n}$ is to be multiplied by a normalized leading-edge flap position in the appropriate reconstruction equation. The change in total coefficient per degree of differential leading-edge flap is given by:

\[
C_{Y\Delta \delta_n} = 0.0 \quad \text{(5.38.a)}
\]

\[
C_{\ell\Delta \delta_n} = \begin{cases} 
F_{C1FDDN} \left( \bar{q}_1, M|^{2} \right) & |\alpha| \leq 40^\circ \\
0.0 & \alpha > 40^\circ
\end{cases} \quad \text{(5.38.b)}
\]

\[
C_{\ell\Delta \delta_n} = 0.0 \quad \text{(5.38.c)}
\]

where:

\[
\bar{q}_1 = \begin{cases} 
\bar{q} & \text{LQSE=.T.} \\
0.0 & \text{LQSE=.F.}
\end{cases}
\] (5.39)

5.5.3 Trailing-Edge Flap Effects ($Y, l, n$)

Increments due to full 20 degree deployment of symmetric trailing-edge flaps in the presence of nonzero sideslip are,

\[
\Delta C_{X\delta_f} = \begin{cases} 
\frac{\beta}{|\beta|} k_{\delta_f} F_{DCXDF} \left( |\beta|^{20}, \alpha|^{40}, M|^{9} \right) & |\alpha| \leq 40^\circ \\
0.0 & \alpha > 40^\circ
\end{cases}
\] (5.40)

where as in the case of the leading-edge flaps, $\Delta C_{X\delta_f}$ is multiplied by normalized trailing-edge flap position in the appropriate reconstruction equation, and the factor $k_{\delta_f}$ is defined as,

\[
k_{\delta_f} = \frac{1.1-M}{2} |\beta|^{1} \quad \text{(5.41)}
\]

The change in total coefficient per degree of differential trailing-edge flap is given by,

\[
C_{Y\Delta \delta_f} = 0.0 \quad \text{(5.42.a)}
\]
\[
C_{l\Delta \delta_f} = \begin{cases} 
F_{\text{CIFDF}}(\alpha_{40}^{20}, H_{SL}^{60000}, M_{\frac{1}{2}}) & \alpha \leq 40^\circ; \text{LQSE}=\text{T.} \\
F_{\text{CIFDF}}(\alpha_{40}^{20}, H_{SL}=60000, M_{\frac{1}{2}}) & \alpha \leq 40^\circ; \text{LQSE}=\text{F.} \\
0.0 & \alpha > 40^\circ
\end{cases} (5.42\text{.b})
\]

\[
C_{n\Delta \delta_f} = 0.0 (5.42\text{.c})
\]

5.5.4 Aileron Effects \((Y, l, n)\)

The increments due to left and right aileron deflection are given by,

\[
\Delta C_x\delta_{A_{L,R}} = \begin{cases} 
k F_{\text{DCXDA}} (\alpha_{40}^{40}, \delta_{A_{L,R}}^{25}, M_{\frac{1}{2}}) & \alpha \leq 40^\circ \\
k F_{\text{HDCXDA}} (\alpha_{90}^{90}, \delta_{A_{L,R}}^{25}, M_{\frac{1}{2}}) & \alpha > 40^\circ
\end{cases} (5.43)
\]

where \(k = 1\) for the left aileron and \(k = -1\) for the right aileron.

The elastic/rigid ratio for aileron effectiveness is,

\[
R_{C_{Y\delta_A}}^F = \begin{cases} 
F_{\text{FRCYDA}} (M_{\frac{1}{2}}, H_{p_{60000}}) & \text{LQSE}=\text{T.} \\
1.63 & \text{LQSE}=\text{F.}
\end{cases} (5.44\text{.a})
\]

\[
R_{C_{l\delta_A}}^F = \begin{cases} 
F_{\text{FRCLDA}} (M_{\frac{1}{2}}, H_{p_{60000}}) & \text{LQSE}=\text{T.} \\
1.25 & \text{LQSE}=\text{F.}
\end{cases} (5.44\text{.b})
\]

\[
R_{C_{n\delta_A}}^F = \begin{cases} 
F_{\text{FRCND}} (M_{\frac{1}{2}}, H_{p_{60000}}) & \text{LQSE}=\text{T.} \\
1.25 & \text{LQSE}=\text{F.}
\end{cases} (5.44\text{.c})
\]

The elastic/rigid ratios assume values other than one in the rigid limit for the same reasons as discussed in section 5.3.3 of this report. The tabular look-up wind-tunnel data was taken before a configuration change that increased aileron area.

5.5.5 Rudder Effects \((Y, l, n)\)

Increments due to antisymmetric (both t.e.left) rudder deflection are given by:

\[
\Delta C_x\delta_R = \begin{cases} 
\frac{\delta_R}{|\delta_R|} F_{\text{DCXDR}} (\alpha_{40}^{40}, |\delta_R|^{30}, M_{\frac{1}{2}}) & \alpha \leq 40^\circ \\
F_{\text{HDCXDR}} (\alpha_{40}^{90}, \beta_{10}^{10}, \delta_R) & \alpha > 40^\circ
\end{cases} (5.45)
\]
The flex/rigid ratio for the effect of antisymmetric rudder is:

$$\frac{R}{C_{X\delta R}} = \begin{cases} \frac{F_{FRXRD\alpha}^{2}, H_{p}^{60000}}{1.0} & \text{LQSE=.T.} \\ \frac{F_{FRXRD\alpha}^{2}, H_{p}^{60000}}{1.0} & \text{LQSE=.F.} \end{cases} \quad (5.46)$$

An additional effectiveness factor that incorporates the effect of symmetric stabilator on the increment due to antisymmetric rudder at high angle of attack is given by,

$$\frac{R}{C_{X\delta H}} = \begin{cases} \frac{F_{HRXRD\alpha}^{2}, H_{p}^{60000}}{1.0} & \alpha > 40^\circ; "X"="n" \\ \frac{F_{HRXRD\alpha}^{2}, H_{p}^{60000}}{1.0} & \text{otherwise} \end{cases} \quad (5.47)$$

5.5.6 **Stabilator Effects** $(Y,l,n)$

The derivative with respect to a differential stabilator, which is itself a function of angle of attack, symmetric stabilator, and Mach, is given by,

$$C_{X\Delta H} = \begin{cases} \frac{F_{CXDD\alpha}^{2}, H_{p}^{60000}}{1.0} & \alpha \leq 40^\circ \\ \frac{F_{HCXDD\alpha}^{2}, H_{p}^{60000}}{1.0} & \alpha > 40^\circ \end{cases} \quad (5.48)$$

The elastic/rigid ratio on the differential tail derivative is defined as,

$$\frac{R}{C_{X\Delta H}} = \begin{cases} \frac{F_{FRXDDH\alpha}^{2}, H_{p}^{60000}}{1.0} & \text{LQSE=.T.}; "X"="Y"or"l" \\ \frac{F_{FRXDDH\alpha}^{2}, H_{p}^{60000}}{1.0} & \text{LQSE=.T.}; "X"="n" \end{cases} \quad (5.49)$$

5.5.7 **Dynamic Derivatives** $(Y,l,n)$

The derivatives due to nondimensionalized roll rate are defined as,

$$C_{Xp} = \begin{cases} \frac{F_{CXp\alpha}^{2}, H_{p}^{60000}}{1.0} & \alpha \leq 40^\circ; "X"="l"; \text{LQSE=.T.} \\ \frac{F_{CXp\alpha}^{2}, H_{p}=60000}{} & \alpha \leq 40^\circ; "X"="l"; \text{LQSE=.F.} \\ \frac{F_{CXp\alpha}^{2}, H_{p}^{60000}}{1.0} & \alpha > 40^\circ; "X"="Y"or"n" \end{cases} \quad (5.50)$$

while the effect of nondimensional yaw rate is given by,
The increment to yaw damping due to elastic deformation is given by,

\[
\Delta C_{Xf}^F = \begin{cases} 
F_{FD\text{CXRF}} (M_{\perp 2}, H_{\rho}l_{0}^{60000}) & \text{LQSE= .T.} \\
0.0 & \text{LQSE= .F.}
\end{cases}
\] (5.52)

A separate flex/rigid ratio on roll damping is calculated for side-force and yawing moment. The flexible effect on roll moment due to roll rate is included in the function used to calculate $C_{l\rho}$:

\[
R_{Cy}\rho F = \begin{cases} 
F_{FR\text{CYP}} (M_{\perp 2}, H_{\rho}l_{0}^{60000}) & \text{LQSE= .T.} \\
0.0 & \text{LQSE= .F.}
\end{cases}
\] (5.53)

\[
R_{Fnp} F = \begin{cases} 
F_{FR\text{CNP}} (M_{\perp 2}, \alpha^{40}_{0}) & \text{LQSE= .T.} \\
F_{FR\text{CNP}} (M_{\perp 2}, \alpha^{40}_{0}) & \text{LQSE= .F.}
\end{cases}
\] (5.54)

\[
R_{F_{cl}^F} = 1.0 \text{ all conditions}
\] (5.55)

5.5.8 Speed Brake Effects ($Y,l,n$)

The speed brake increments shown below are due to full, normalized, speed brake deployment and are multiplied by sideslip angle in the reconstruction equations.

\[
\Delta C_{XsB} = \begin{cases} 
 \left( \frac{\delta_{SB}}{60} \right) F_{DC\text{XS}B} (\alpha^{40}_{\perp 10}, [\beta]^{20}_{0}, M_{\perp 2}) & \alpha \leq 40^\circ \\
\left( \frac{45 - \alpha}{5} \right) \left( \frac{\delta_{SB}}{60} \right) F_{HDC\text{XS}B} (\beta_{10}^{10}, M_{\perp 2}) & \alpha > 40^\circ
\end{cases}
\] (5.56)

5.5.9 Effect of Airplane Asymmetries ($Y,l,n$)

A rolling moment is induced at zero sideslip and symmetric controls for angle of attack between $45^\circ$ and $60^\circ$. This rolling moment is attributed (section 4.1.2 of [MDC A7247, vol. 2]) to asymmetries in the nose. The asymmetric increment is given by,
\[
\Delta C_{\text{asm}} = \begin{cases} 
0.0 & \alpha \leq 40^\circ \\
F_{\text{HC1ASM}} \left( \alpha \right) & \alpha > 40^\circ; "X" = "1"; \text{LRTE} = .F. \\
0.0 & \alpha > 40^\circ; "X" = "1"; \text{LRTE} = .T. \\
0.0 & \alpha > 40^\circ; "X" = "Y" \text{ or } "n" 
\end{cases} 
\] (5.57)

5.6 Force and Moment Calculations

In this section we describe how the total aerodynamic forces and moments at the c.g. are calculated. The aerodynamic model has been worked up about an aerodynamic reference center. While it is common practice to transform the outputs of the aerodynamic model (force and moment coefficients) from the aerodynamic reference center to the c.g., it is less common to transform the inputs to the aerodynamic model. Both transformations are performed in the fl8bas simulation in the interest of completeness. The practice of transforming the inputs has been seen by the authors in a simulation model for the X-29 and in section II of Gainer and Hoffman (1972).

First, the velocity of the air is subtracted from the inertial translational velocity of the airplane to get relative velocity (with respect to the air mass) at the c.g. The body frame components of velocity with respect to the air mass are given by,

\[
\begin{bmatrix}
u_a \\
v_a \\
w_a \\
\end{bmatrix} = \begin{bmatrix}
u \\
v \\
w \\
\end{bmatrix} - \begin{bmatrix}
u_{wg} \\
v_{wg} \\
w_{wg} \\
\end{bmatrix}
\] (5.58)

where \([\nu_{wg} \, v_{wg} \, w_{wg}]^T\) is the velocity of the air due to winds, turbulence, and gusts.

The velocity components relative to the air mass at the a.r.c. are given by,

\[
\begin{bmatrix}
u_{arf} \\
v_{arf} \\
w_{arf} \\
\end{bmatrix} = \begin{bmatrix}
u_a \\
v_a \\
w_a \\
\end{bmatrix} + \begin{bmatrix}0 & -r & q \\r & 0 & -p \\-q & p & 0 \end{bmatrix} \begin{bmatrix}x_{arf} \\
y_{arf} \\
z_{arf} \\
\end{bmatrix}
\] (5.59)

where \([x_{arf} \, y_{arf} \, z_{arf}]^T\) locates the a.r.c. in the c.g.-centered body frame. Rotational velocities at the c.g. can induce small changes in translational velocities at the a.r.c. Incidence angles (\(\alpha_{arf}\) and \(\beta_{arf}\)), airspeed, and Mach number, are then computed from relative velocities at the a.r.c.

\[
\begin{align*}
\alpha_{arf} &= \arctan\left( \frac{w_{arf}}{u_{arf}} \right) \\
\beta_{arf} &= \arcsin\left( \frac{v_{arf}}{V_{rf}} \right) \\
V_{rf} &= \sqrt{\frac{u_{arf}^2 + v_{arf}^2 + w_{arf}^2}{a}} \\
M_{rf} &= \frac{V_{rf}}{a}
\end{align*}
\] (5.60)
Dynamic pressure ($\dot{q}$) is left referenced to the c.g. The dynamic pressure in lbs/ft$^2$ is given by,

$$\dot{q} = \frac{1}{2} \rho V_{rf}^2$$  \hspace{1cm} (5.61)

where $\rho$ is the density in slugs/ft$^3$. A density altitude, $H_p$, is calculated from the air density, $\rho$. $H_p$ is the altitude in feet that is appropriate for $\rho$ in the 1962 Standard Atmosphere tables. Air density can be varied as an independent variable if required (e.g., hot day conditions).

### 5.6.1 Steady Flow Outputs

The quantities defined in equations (5.60) and (5.61) are then combined with the body frame rotational rates ($p,q,r$), pressure altitude, the control surface deflections ($\{\delta\}$), and the reference dimensions ($c,b$), to serve as inputs to the aerodynamic model described in sections 5.2 through 5.5. Outputs of the aerodynamic model include the force and moment coefficients for steady flow conditions. The process is characterized by equation 5.62.

$$C_{\|sf} = f_{\text{aero}}(\alpha_{rf}, \beta_{rf}, V_{rf}, M_{rf}, \dot{q}, H_p, \{\delta\}, p, q, r, c, b)$$  \hspace{1cm} (5.62)

where "$l$" = "L", "D", "Y", "T", "m", or "n". The lift and drag coefficients are converted to body axis components via,

$$\begin{align*}
C_{X_{sf}} &= -\cos(\alpha_{rf})C_{D_{sf}} + \sin(\alpha_{rf})C_{L_{sf}} \\
C_{Z_{sf}} &= -\sin(\alpha_{rf})C_{D_{sf}} - \cos(\alpha_{rf})C_{L_{sf}}
\end{align*}$$  \hspace{1cm} (5.63)

The steady flow aerodynamic forces in the body frame are given by,

$$\begin{bmatrix} F \end{bmatrix}_A \bigg|_{V=0} = \begin{bmatrix} F_{X_{sf}} \\ F_{Y_{sf}} \\ F_{Z_{sf}} \end{bmatrix}_A = \dot{q}S \begin{bmatrix} C_{X_{sf}} \\ C_{Y_{sf}} \\ C_{Z_{sf}} \end{bmatrix}_A$$  \hspace{1cm} (5.64)

The steady flow aerodynamic moments in the body frame are given by,

$$\begin{bmatrix} M \end{bmatrix}_A \bigg|_{V=0} = \begin{bmatrix} M_{X_{sf}} \\ M_{Y_{sf}} \\ M_{Z_{sf}} \end{bmatrix}_A = \dot{q}S \begin{bmatrix} b C_{L_{sf}} \\ b C_{m_{sf}} \\ b C_{n_{sf}} \end{bmatrix}_A + \begin{bmatrix} 0 & -z_{arf} & y_{arf} \\ z_{arf} & 0 & -x_{arf} \\ -y_{arf} & x_{arf} & 0 \end{bmatrix} \begin{bmatrix} F_{X_{sf}} \\ F_{Y_{sf}} \\ F_{Z_{sf}} \end{bmatrix}_A$$  \hspace{1cm} (5.65)

As a simple sanity check, observe that a positive $x_{arf}$ implies the a.r.c. is ahead of the c.g., and a positive $F_{Z_{sf}}$ force applied at the a.r.c. induces a negative pitch moment, $M_Y$. 

46
5.6.1 Unsteady Flow Outputs

We seek now to define the $6 \times 6$ apparent mass matrix defined in equation (4.13) (repeated below) that arises from the $C_{L\dot{\alpha}}$ and $C_{m\dot{\alpha}}$ stability derivatives.

$$[M]_A = \frac{\partial \{ F \}_A}{\partial \{ V \}}$$  \hspace{1cm} (4-13)

First, in a process similar to equation (5.63), transform the $\dot{\alpha}$ stability derivatives from stability to body frame components at the a.r.c.,

$$C_{X\dot{\alpha}} = - \cos(\alpha_{rf})C_{D\dot{\alpha}} + \sin(\alpha_{rf})C_{L\dot{\alpha}}$$
$$C_{Z\dot{\alpha}} = - \sin(\alpha_{rf})C_{D\dot{\alpha}} - \cos(\alpha_{rf})C_{L\dot{\alpha}}$$  \hspace{1cm} (5.66)

In the $fl8bas$ simulation, as is typically the case, $C_{D\dot{\alpha}}$ is zero. Define some intermediate terms that have units of mass and mass-length.

$$m_0 = \frac{\dot{c}}{2} \left( \frac{c}{2V_{rf}} \right) \left( \frac{u_{arf}}{u_{arf}^2 + w_{arf}^2} \right) \text{slugs}$$  \hspace{1cm} (5.67)

$$m_u = m_0 C_{X\dot{\alpha}} \text{ slugs}$$
$$m_w = m_0 C_{Z\dot{\alpha}} \text{ slugs}$$
$$m_q = \dot{c} m_0 C_{m\dot{\alpha}} \text{ slug-ft}$$  \hspace{1cm} (5.68)

For notational convenience, let $V$ and $\omega$ denote the $3 \times 1$ column vectors associated with translational and rotational velocity, respectively,

$$V = \begin{bmatrix} u \\ v \\ w \end{bmatrix}, \quad \omega = \begin{bmatrix} p \\ q \\ r \end{bmatrix}$$  \hspace{1cm} (5.69)

The apparent mass matrix is given by,

$$[M]_A = \frac{\partial \{ F \}_A}{\partial \{ V \}} = \begin{bmatrix} [M_{VV}] & [M_{V\omega}] \\ [M_{\omega V}] & [M_{\omega\omega}] \end{bmatrix}$$  \hspace{1cm} (5.70)

where,
\[
\hat{\omega}_{rf} = \begin{pmatrix} \omega_{rf} \\ u_{arf} \end{pmatrix}
\] (5.71)

\[
[M_{V\dot{V}}] = \begin{bmatrix}
 m_u \hat{\omega}_{rf} & 0 & -m_u \\
 0 & 0 & 0 \\
 m_w \hat{\omega}_{rf} & 0 & -m_w
\end{bmatrix}, \text{slugs} \] (5.71)

\[
[M_{V\omega}] = \begin{bmatrix}
 -m_u y_{arf} & m_u (x_{arf} + \hat{\omega}_{rf} z_{arf}) & -m_u \hat{\omega}_{rf} z_{arf} \\
 0 & 0 & 0 \\
 -m_w y_{arf} & m_w (x_{arf} + \hat{\omega}_{rf} z_{arf}) & -m_w \hat{\omega}_{rf} y_{arf}
\end{bmatrix}, \text{slug-ft} \] (5.72)

\[
[M_{\omega V}] = \begin{bmatrix}
 m_w \hat{\omega}_{rf} y_{arf} & 0 & -m_w y_{arf} \\
 (m_u z_{arf} + m_w x_{arf} + m_q) \hat{\omega}_{rf} & m_u z_{arf} + m_w x_{arf} - m_q & \hat{\omega}_{rf} y_{arf} \\
 -m_u \hat{\omega}_{rf} y_{arf} & 0 & m_u y_{arf}
\end{bmatrix}, \text{slug-ft} \] (5.73)

and,

\[
[M_{\omega\omega}] = \\
\begin{bmatrix}
 -m_w y_{arf}^2 & m_w (x_{arf} + \hat{\omega}_{rf} z_{arf}) y_{arf} & -m_w \hat{\omega}_{rf} y_{arf}^2 \\
 (m_u z_{arf} + m_w x_{arf} + m_q) y_{arf} & (m_u z_{arf} + m_w x_{arf} + m_q) (x_{arf} + \hat{\omega}_{rf} z_{arf}) & (-m_u z_{arf} + m_w x_{arf} - m_q) \hat{\omega}_{rf} y_{arf} \\
 m_u y_{arf}^2 & -m_u (x_{arf} + \hat{\omega}_{rf} z_{arf}) y_{arf} & m_u \hat{\omega}_{rf} y_{arf}^2
\end{bmatrix}, \text{slug-ft}^2 \] (5.74)
5.7 Implementation of the aerodynamic model

As described in section 5.1, the aerodynamic force and moment coefficients are calculated in subroutines SFAERRF and USAERRF. In sections 5.7.1 and 5.7.2 the input/output variables of the subroutines SFAERRF and USAERF, respectively, are described.

5.7.1 SFAERRF - Input/Output List

The subroutine SFAERRF produces the total force and moment coefficients about the aerodynamic reference center for steady flow conditions (constant angle of attack and sideslip). The names of each input/output parameter as they appear in both the subroutine (SFAERRF) and in the fl8bas.csl code from which SFAERRF is called, are listed in tables 5.3 and 5.4. The density altitude is used as an input to the flex/rigid multipliers and increments. Ground clearance was used for ground effect calculations. The calculations associated with ground effect have been removed, but the parameter list was left unchanged in the interest of compatibility.

6. ENGINE THRUST MODEL

The engine model takes inputs from the pilot throttle and an autothrottle command, uses current air data (altitude, Mach number, and dynamic pressure), and computes the engine forces acting on the airframe for the equations of motion described in section 4. This engine model is referred to as the "QT Half" model in MDC documentation and correspondence (MDC internal memorandum 338-5250, dated 5-Dec-80, from R.O. Michael and B.R. Williams), and apparently is a refined model (circa 1980) based on installed engine performance flight tests. It should be noted that the authors focused on implementing this model as provided, in order to facilitate comparison with an existing real-time simulation model. The authors are not able to explain some aspects of the architecture of this model -- these will be noted as appropriate in the text below.

The model from pilot/autopilot inputs to thrust determination for a given engine is represented graphically in figure 6.0. Since the airplane has two engines, this model is implemented in code by parallel sets of ACSL equations and external subroutine calls for the left and right engines. Although the autopilot input is provided for future use, in the current simulation this input, CAT, is set to zero. Therefore, PLA, the total throttle command, is equal to CP, the pilot throttle command.

![Figure 6.0. Engine Model Block Diagram](image)

6.1 Throttle Dynamics

PLA is input to the Throttle Dynamics, a straightforward servo model with throttle position, DPL, as its output. This servo model includes a limited integrator, which functions as a normal integrator as long as its output remains between the indicated limits \([31, 130]\). If the integrator output equals or exceeds these limits, the state derivative DPLD is set to zero within the limited integrator macro and the integrator output is appropriately limited. The limited integrator block shown in figure 6.1 is the implementation provided by ACSL's built-in limited integrator command. This structure is shown for graphical convenience; in the ACSL simulation model, a
A custom macro using IF condition tests is actually used. Either implementation should be equivalent; the custom macro was developed by the authors to retain control over the variable names of states and state derivatives [ACSL (1987)].

**Figure 6.1. Throttle Dynamics**

### 6.2 Static Performance

As shown in figure 6.2, throttle position (DPL), along with altitude (H), Mach number (MACH), and an internal engine dynamics state (VAE0) are input to the static performance module (Fortran subroutine ENG1). VAE0 is an artificial state created to break an algebraic loop for the static performance module. In the original specification, VAE is an input into the static performance module, and VAE is dependent on output THRC. VAE0 is created by passing VAE through a fast first order lag and is discussed further in section 6.5, Core Dynamics.

The outputs of the static performance module are engine thrust command (THRC), fuel flow (WF), idle thrust (TIDLE), maximum military power thrust (TMIL), minimum afterburner thrust (TAUGMN), maximum afterburner thrust (TAUGMX), and various gains and parameters for the engine dynamics (TESTV, GKI, TAU, P1, P2, TAU). THRC and WF are each computed as a table-lookup function, of H, MACH, and DPL. There are two table-lookup functions for THRC; one for military power throttle settings and one for afterburner throttle settings.

**Figure 6.2. Static Engine Performance**

The authors cannot fully explain the internal architecture of the static performance module -- the switch between the Core and the Augmented (afterburner) Thrust Command lookup tables occurs
at a DPL (PLA after dynamics) of 106.5°, rather than the expected military/afterburner throttle position boundary of 88-91° (PLA).

TIDLE, TMIL, TAUGMN, and TAUGMX are computed for appropriate fixed throttle positions using the same table-lookup function as for THRC. TESTV, GK1, P1, P2, TAU are computed as table-lookup functions of VAE0.

THRC is used by two sets of engine dynamics running in parallel: Afterburner Dynamics and Core Dynamics. This will be described further below. GK1, TAU, TESTV, and TMIL are used in the Core Dynamics (see below). TAUGMN is used in the Discrete Event Logic (see below). WF, TIDLE, and TAUGMX are not currently used elsewhere in the ACSL simulation model.

6.3 Discrete Event Logic

As described above, the engine thrust command (THRC) is provided to two sets of engine dynamics running in parallel: Afterburner Dynamics and Core Dynamics. These dynamics provide a single thrust output that is used as the total net thrust for a given engine. The Discrete Event Logic (figure 6.3) is used to determine when to switch from one set of dynamics to the other, and implements code:

1) to select the appropriate thrust output from either Afterburner Dynamics or Core Dynamics;
2) to enable a smooth transition between the two dynamic systems by updating appropriate state variables -- this is accomplished in ACSL using DISCRETE blocks (one per engine) called by the ACSL SCHEDULE operator [ACSL (1987)].

The authors note that the Discrete Event Logic uses a thrust comparison test that is inconsistent with the switch test used in the static performance module to select the output of the thrust table lookup. The authors cannot explain why this is so; nor can we explain why this parallel dynamics architecture was chosen. It would seem more physically intuitive to implement an Afterburner Dynamics module that outputs an incremental thrust to be added to the Core Dynamics thrust to yield total net thrust.

![Discrete Event Logic](image-url)
6.4 Afterburner Dynamics

As shown in figure 6.4, THRC is one of three inputs to the Afterburner Dynamics. The physics of the MDC model are such that when the thrust command (THRC) exceeds the afterburner thrust (TAB), TAB integrates up at the rate ABUL. Conversely, when TAB is greater than THRC, TAB integrates down at the rate ABLL.

ABUL and ABLL are computed based on current values of altitude (H) and dynamic pressure (QBAR). The lower rate limit, ABLL, is computed as a function of H,

\[
ABLL = 0.0275H - 5500 \quad (6.1)
\]

The upper rate limit, ABUL, is computed in two steps. The first step is to compute an intermediate value as a function of QBAR,

\[
ABUL^* = 1.7QBAR^2 - 12.8QBAR + 3000 \quad (6.2)
\]

ABUL is then computed by limiting ABUL* as,

\[
ABUL = \begin{cases} 
900 & ABUL^* < 900 \\
ABUL^* & 900 \leq ABUL^* \leq 4000 \\
4000 & 4000 < ABUL^*
\end{cases} \quad (6.3)
\]

In the ACSL implementation of this system, the error signal THRC minus TAB is multiplied by a large gain (200) to yield ZZAB. ZZAB is passed through a rate limiter and is appropriately limited to ABUL or ABLL to yield RTAB. RTAB is then integrated to yield TAB. Synchronization of the Afterburner Dynamics with the Core Dynamics is achieved by updating TAB with the last value of core engine thrust, TT, when transition from Core Dynamics to Afterburner Dynamics occurs. This has the effect of "restarting" the afterburner dynamics from the thrust value at transition.

![Figure 6.4. Afterburner Dynamics](image)
6.5 Core Dynamics

As shown in figure 6.5, THRC is one of two primary inputs to the Core Dynamics, which implements a second order dynamics approximation to a more complicated, higher order dynamic model of the turbomachinery used for batch analysis of the engine by its manufacturer. The other five inputs are variables that have been described previously: TESTV, GK1, P1, P2, TAU.

The error signal VAC is computed by subtracting VAF from THRC. VAC is multiplied by the gain GK1 and is passed through the rate limiter bounded by limits RTEUL and RTELL to yield VAE. The rate limits RTEUL and RTELL are the engine spool-up/down rate limits and are defined as CONSTANT variables in the ACSL simulation model. Therefore, although they have a "default" value, these limits can be altered at runtime [ACSL (1987)] by the user. The default values are ±5500.

![Diagram of Core Dynamics](image)

Figure 6.5. Core Dynamics

VAE is input to a low-pass filter to generate the artificial state VAE0 as described earlier to break the algebraic loop for the static performance module. The time constant for this filter is sufficiently small (50 rad/sec) to insure that all engine dynamics are unaffected by the filter. VAE is input to an integrator, yielding VAF. Synchronization of this integrator with the Afterburner Dynamics is achieved by updating VAF with the last value of afterburner engine thrust, TAB, when transition occurs from Afterburner Dynamics to Core Dynamics. This has the effect of "restarting" this integrator with the thrust value at transition.
VAF is the major component of the core engine thrust, represented by a rate-limited first order lag. VAF is used to form the error signal VAC as previously described. VAF is tested against TAUGMN in Discrete Event Logic to determine whether to initiate a transition between Core Dynamics and Afterburner Dynamics. VAF is supplied to the "Nonlinear Switch" [MDC internal memo 338-5250]. The "Nonlinear Switch" will be described below. VAF is summed with VAK to determine core engine thrust, TT.

The "Nonlinear Switch" can only be active when the core dynamics are being used. Inputs to this switch are VAF, VAC, TMIL and TESTV. At each simulation time step for which the condition

\[ \text{ABS} \left( \frac{VAC}{TMIL} \right) < \text{TESTV} \]  

is true, the "Nonlinear Switch" assigns VAH to the current value of VAF. Since the "Nonlinear Switch" is the only mechanism for defining VAH, it remains constant when the above condition is not true. TMIL is a function of Mach number and altitude; TESTV is a positive-valued function of VAE/TMIL, varying proportionally with the magnitude of VAE. Therefore VAH only changes when VAC is large relative to VAE (big change in throttle command).

Subroutine ENG2, coded in FORTRAN, is only called when the core dynamics are being used. The input is an internal engine dynamics parameter \( \frac{VAF}{TMIL} \). The output is a gain for the second order dynamics block (GK3).

VH1 is subtracted from VAH and the result is divided by TAU, yielding VH1D. VH1D is integrated to give VH1. Synchronization of this integrator with the Afterburner Dynamics is achieved by setting VH1 equal to VAH when transition occurs from Afterburner Dynamics to Core Dynamics. By "zeroing" the input signal to this integrator, this part of the dynamics is not active at transition.

VH1D is input to the 2nd Order Dynamics block, a transfer function with the following Laplace expression,

\[ \frac{VAK}{VH1D} = \frac{(P2)^2(GK3)}{S^2 + 2(P1)(P2)S + (P2)^2(GK3)} \]  

The VAK term provides the small "ballooning" effect for the engine described in MDC internal memo 338-5250 (1980). VAK is summed with VAF to give the total thrust for the Core Dynamics, TT.

6.6 Total Engine Thrust

The final total thrust for each engine, TH, is determined by the position of the AB/Core switch. If THRF ≥ 0, then TH is equal to the output of the Core Dynamics, TT; otherwise, TH is equal to the output of the Afterburner Dynamics, TAB.

6.7 Calculations for Equations of Motion

The equations of motion for the simulation, described in section 4, require the 3-axis body frame components of force and moment due to the thrust from the engines. Therefore, operations are performed on the final total thrust for each engine, TH, and then added together to yield these required force/moment components. Note that engine gyroscopic moment effects are not modeled.
In keeping with overall assumptions that an x-z plane of symmetry exists, the engines are assumed to be located symmetrically with respect to the body frame x-z plane. However, the thrust axis of each engine is not parallel to the x-axis. Each engine is canted out slightly (1.98") so that the exit nozzles are closer to the airplane centerline than the front of the engines. The pitch or elevation angle of each engine is zero. Engine cant is measured by an azimuth angle ($\Psi_{\text{eng}}$) that represents rotation about the body frame z-axis. Given this information, the body-axis components of thrust for each engine are computed as,

$$
\begin{align*}
TH_x; L &= TH_L \cos(\Psi_{\text{eng} L}) \\
TH_y; L &= TH_L \sin(\Psi_{\text{eng} L}) \\
TH_z; L &= 0 \\
TH_x; R &= TH_R \cos(\Psi_{\text{eng} R}) \\
TH_y; R &= TH_R \sin(\Psi_{\text{eng} R}) \\
TH_z; R &= 0
\end{align*}
$$

(6.6)

where the subscripts "L" and "R" denote left and right engines, and where,

$$
\Psi_{\text{eng} L} = -1.98^\circ \text{ and } \Psi_{\text{eng} R} = 1.98^\circ
$$

(6.7)

The force quantities for the equations of motion can now be computed,

$$
\begin{align*}
FX_E &= TH_x; L + TH_x; R \\
FY_E &= TH_y; L + TH_y; R \\
FZ_E &= TH_z; L + TH_z; R
\end{align*}
$$

(6.8)

The engine thrust is assumed to be applied where the thrust axis intersects the "engine/airframe interface", defined in the engineering drawing, figure 3.1. As can be seen from figure 3.1, the location of the "engine/airframe interface" for the right engine is defined in the FS/BL/WL coordinate frame as (687.5, 18.9, 100.0). The interface point for the left engine is (687.5, -18.9, 100.0). This information is specified in the variables $F_{\text{SENG}}$, $B_{\text{LENG} R}$, $B_{\text{LENG} L}$, and $W_{\text{LENG}}$ in CONSTANT statements in the $fl8bas$ simulation. The vector that locates the engine/airframe interface point in the c.g.-centered body frame is computed in units of feet for use in calculating the moments about the c.g.,

$$
\begin{align*}
x_{\text{erf}} &= -(F_{\text{SENG}} - F_{\text{SCG}}) / 12 \\
y_{\text{erf} R} &= (B_{\text{LENG} R} - B_{\text{LCG}}) / 12 \\
y_{\text{erf} L} &= (B_{\text{LENG} L} - B_{\text{LCG}}) / 12 \\
z_{\text{erf}} &= -(W_{\text{LENG}} - W_{\text{LCG}}) / 12
\end{align*}
$$

(6.9)

The calculations of (6.9) are performed once in the initialization phase of the simulation. Given this information, the moment quantities for the equations of motion can now be computed,

$$
\begin{align*}
M_{X E} &= -z_{\text{erf}} FY_E + y_{\text{erf} R} TH_z; R + y_{\text{erf} L} TH_z; L \\
M_{Y E} &= z_{\text{erf}} FX_E - x_{\text{erf}} FZ_E \\
M_{Z E} &= -(y_{\text{erf} R} TH_x; R + y_{\text{erf} L} TH_x; L) + x_{\text{erf}} FY_E
\end{align*}
$$

(6.10)
7. SENSORS

The sensor code was taken from the LaRC real-time simulation (dmsf18). These models can also be found in subroutine FCSENS of the MDC simulation of the F/A-18. A table of sensor characteristics can be found in figure 7-7 of [MDC A7813, vol I, rev A, page 7-16] and selected parts are repeated below as Table 7.1. In the dmsf18 simulation, the sensor calculations and dynamics are performed in the same subroutines that model the control laws. In keeping with a policy of modeling all continuous dynamics in the derivative portion of the ACSL simulation, sensor MACRO's were written to implement the sensor models, and the sensor code was stripped out of the control law subroutines that are called from the FCS discrete block.

The sensor values used by the flight control system model can be either the ideal values or values computed using various sensor models. The variable ISENS determines which type of sensor data is sent to the flight control subroutines. The ISENS variable was made integer type in order to accommodate multiple sensor models. The simulation currently calculates two sets of sensor outputs. The first set consists of the variables created by adding a "0" to the variable names in table 7.2, i.e. \{ALFS0, AYS0, ..., PSTS0\}, and represents ideal sensors. The second set consists of the variables created by adding a "1" to the list in Table 7.2, i.e. \{ALFS1, AYS1, ..., PSTS1\}, and represents the sensor models used in the MDC simulation. At one time, a third, more complex, set of sensor models was implemented in the AGCB simulation to produce the variable set \{ALFS2, AYS2, ..., PSTS2\}. The ISENS=2 option was removed to reduce complexity and because it was not entirely integrated with the simulation trimming algorithm, but could be reinstalled if the need arose. The final output variables in Table 7.2 are determined from the sensor model sets according to the value of the integer switch, ISENS, as shown in figure 7.1.

```
IF (ISENS=0) THEN
  ALFS = ALFS0
  PSTS = PSTS0
ELSE
  ALFS = ALFS1
  PSTS = PSTS1
END IF
```

Figure 7.1. Code block that selects sensor model
The sensor equations appear in both the initial section of the program code and in the derivative section. The initial section contains full code for the computations. The derivative section makes use of macros which appear at the top of the ACSL program as ACCEL1, ALGBT1, PITOT, and RGYRO1.

Ideal static pressure (PSTATC) is computed from the aircraft altitude (H, Height, in the main loop, HIC, Height Initial Condition, in the initial section) through the subroutine call to PSTAT. It interpolates for the static pressure value from an single independent variable (H) ATMAT62 data table. Ideal compressible impact pressure (QC) is computed from the ideal static pressure (PSTATC) and the Mach number (MACH, for main loop, MACHTR, MACH TRim, for the initial section) through the subroutine CPRESS. It interpolates for the compressible impact pressure from a two independent variable (MACH and PSTATC) data table.

Sensed static pressure (PSTS1, ISENS = 1) is computed from the ideal pressure divided by a scaling factor, SPSFXD. SPSFXD is computed as a function of Mach number and sensed angle of attack (ALFS1). The QCDA, QCDB...QCDH variables which appear in the scaling equation are a function of Mach number and are defined as constants in the initial section of the program code. The sensed compressible pressure (QCIS1, ISENS=1) is also determined as a function of Mach and angle of attack, where the static pressure is added to the ideal compressible pressure before the computation and then removed afterwards. A final computation is then made based on a limited angle of attack. These computations model the Pitot tube and static probe mechanics, where the measured value, as determined by pressure differentials, does not exactly reflect the true air pressure values. These pressure values are used in the flight control system for air data scheduling. The air data scheduled gain values were designed to be scheduled from measured pressure values and not the true or ideal pressures.

Sensed angle of attack is computed from the true angle of attack with a gain and bias based on air flow. The bias, (ALFB), is determined by the landing gear position, if the landing gear is retracted (the normal position for any runs) ALFB=1.9, extended ALFB=1.2. The gain, GKAOA, (where it is divided into the true alpha minus the bias) is a function of the Mach number. The measured angle of attack is limited to -14 and 56 degrees.

7.1 Ideal Static Pressure and Compressible Impact Pressure

Static pressure, PS, is calculated as a function of altitude in feet by the subroutine PSTAT. The function,

\[ P_S, \text{ lbs/ft}^2 = F_{PSTAT}(H) \]

implemented in subroutine PSTAT is plotted in figure 7.2.
Subroutine CPRESS calculates compressible dynamic pressure as a function of Mach and static pressure, $P_S$, as follows:

$$Q_C = (Q_C/P_S) \cdot P_S$$

where the ratio $Q_C/P_S$ is a function of Mach number and is given by figure 7.3. The subroutines PSTAT and CPRESS are called from the DERIVATIVE block.
7.2 Ideal Sensor Set (ISENS=0)

\[ \alpha_{s0} = \alpha, \text{ degrees} \]
\[ n_{y_{s0}} = n_y, \text{ g's} \]
\[ n_{z_{s0}} = -n_z - 1, \text{ g's} \]
\[ p_{s0} = (180/\pi)p, \text{ \(^*/sec\)} \]
\[ q_{s0} = (180/\pi)q, \text{ \(^*/sec\)} \]
\[ r_{s0} = (180/\pi)r, \text{ \(^*/sec\)} \]
\[ Q_{c_{s0}} = Q_c, \text{ PSF} \]
\[ P_{s_{s0}} = P_s, \text{ PSF} \]

where,

\[ n_y = (\ddot{v} + ru - pw - gy_z) / g \]
\[ n_z = (\dot{w} + pv - qu - gz_z) / g \]

7.3 Accelerometers (ISENS=1)

The calculations for the lateral and vertical accelerometers are performed in the macro ACCEL1. The lateral accelerometer output, AYS1, is positive for an acceleration to the right and the vertical accelerometer output, AZS1, is positive for an upward acceleration. Both AYS1 and AZS1 have units of g's. Lever arm effects are calculated and the 1 g bias removed from AZS1. Both outputs are bounded according to Table 7.1.a. Hysteresis, bias, quantization and misalignment are not modeled in the MDC sensor set. The MDC simulation, mdcf18, has comments that refer to a transfer function of \( G(s) = (s/220)^n \) that approximates the accelerometer dynamics, but was deleted from the MDC simulation. The fl8bas simulation does not model accelerometer dynamics either. The location of the accelerometers in the body frame in feet is given by,

\[ x_a = -(FS_a - FS_{cg}) / 12. \]
\[ y_a = (BL_a - BL_{cg}) / 12. \]
\[ z_a = -(WL_a - WL_{cg}) / 12. \]
where \(x_a, y_a, z_a\) represent distances in feet forward from the c.g., right of the c.g. and below the c.g., respectively, and where,

\[
\begin{align*}
F_{Scg} & = FSCG, \text{ Fuselage Station c.g.} = 455.0 \text{ inches} \\
B_{Lcg} & = BLCG, \text{ Buttock Line c.g.} = 0.0 \text{ inches} \\
W_{Lcg} & = WLCG, \text{ Water Line c.g.} = 102.8 \text{ inches} \\
F_{S_a} & = \text{NYLOC(1)} = 306.75 \text{ inches} \\
B_{L_a} & = \text{NYLOC(2)} = 10.5 \text{ inches} \\
W_{L_a} & = \text{NYLOC(3)} = 91.3 \text{ inches}
\end{align*}
\]

The lateral and vertical accelerations with lever arm effects included and 1 g bias removed are,

\[
\begin{align*}
ny_s &= ny + \frac{(pq + r)x_a - (p^2+r^2)y_a + (qr-p)z_a}{g} \\
nz_s &= -1 - nz - \frac{(pr-q)x_a + (qr+p)y_a - (p^2+q^2)z_a}{g}
\end{align*}
\]

The ISENS=1 output accelerations are bounded according to table 7-1a.

\[
\begin{align*}
ny_{s1} &= ny_s^{\frac{1}{2}} \quad \text{(AYS1)} \\
nz_{s1} &= nz_s^{10} \quad \text{(AZS1)}
\end{align*}
\]

### 7.4 Rate Gyros (ISENS=1)

The outputs of the rate gyros are simply the body frame roll, pitch, and yaw rates in units of degrees/sec with limits applied as indicated in table 7.1a. The calculations are performed in macro RGYRO1 as follows,

\[
\begin{align*}
\rho_{s1} &= \left(\frac{180}{\pi}\right) \left(\frac{300}{300}\right) \text{\degree/sec} \quad \text{(PS1)} \\
q_{s1} &= \left(\frac{180}{\pi}\right) \left(\frac{60}{-60}\right) \text{\degree/sec} \quad \text{(QS1)} \\
r_{s1} &= \left(\frac{180}{\pi}\right) \left(\frac{60}{-60}\right) \text{\degree/sec} \quad \text{(RS1)}
\end{align*}
\]
7.5 Angle of Attack Measurement (ISENS=1)

The angle-of-attack probe model is implemented in macro ALFBT1. The "probe" quantity is calculated by passing the angle of attack at the c.g. through a filter representing the probe dynamics,

\[ \alpha_p = \left( \frac{1}{0.073 s + 1} \right) \alpha \]

The local probe angle of attack is adjusted for the induced upwash due to pitch rate,

\[ \alpha_{p1} = \alpha_p - (180/\pi) \frac{l_p q}{V} \]

where \( l_p = 24 \) feet. From purely geometric consideration, one would expect \( l_p \) to be the distance from the center-of-gravity to the angle-of-attack probe where \( l_p \) has units of feet and is positive if the probe is forward of the c.g. A probe located at a fuselage station (FS) of 167 inches is consistent with \( l_p = 288 \) inches and a nominal c.g. location of \( F_{S_{cg}} = 455.0 \) inches, placing the probe between the nose (FS=60.50) and the leading edge of the cockpit (FS=188.0) (see figure 3.1). However, one must wonder why the probe dynamics are not applied to the total local measurement that includes pitch rate effects instead of to the angle of attack at the c.g. At this point, the only answer is that this is the way it is done in subroutine FCSENS of the MDC simulation.

An angle-of-attack probe bias and gain inverse are calculated. The bias is given by,

\[ \alpha_{p\text{bias}} = \begin{cases} 1.9 \text{ degrees if gear up} \\ 1.2 \text{ degrees if gear down.} \end{cases} \]

The gain inverse is a function of limited Mach number,

\[ GK_\alpha = FGKAOA( M, \frac{1.9}{1.4} ) \]

where the function \( FGKAOA \) is defined by figure 7.4.

The final limited sensor output is then,

\[ \alpha_{s1} = \frac{\alpha_{p1} - \alpha_{p\text{bias}}}{GK_\alpha} \left[ \begin{array}{c} 56 \\ -14 \end{array} \right] \quad (ALFS1) \]
7.6 Air Data Parameters (ISENS=1)

The calculation of indicated static pressure and indicated compressible dynamic pressure requires eight parameters, QCDx, where x={A,B,...,H}. The QCDx are 21 element arrays and the current value for each QCDx parameter is determined as a tabular function of Mach. XHM1 is the similarly sized independent variable array of Mach numbers with a maximum value of 1.65 and a minimum of 0. A search is performed to determine the integer IxHM such that XHM1(IxHM) ≤ Mach < XHM1(IxHM+1). The IxHM th elements of the QCDx arrays are used in the following calculations. No interpolation is done on the QCDx variables. In the notation below, QCDx = QCDx(IxHM). The QCDx parameters as functions of Mach are plotted in figure 7.5.a-h.

The calculation of the sensed static pressure for ISENS=1, PSs1, is shown in equations 7.1 through 7.3.

\[
S_{PSFXD} = 1 - Q_{CDBM} - Q_{CDA} - (Q_{CDBM} + Q_{CDE})\alpha_{S1} \quad (7.1)
\]

\[
P_{S1} = P_S / S_{PSFXD} \quad (7.2)
\]

\[
PTS1 = P_{S1} \quad (7.3)
\]

The calculation of indicated compressible dynamic pressure is shown in equations 7.4 through 7.8.

\[
PT = Q_c + P_S \quad (7.4)
\]

\[
PT1 = \frac{PT}{1 - Q_{CDFM} - Q_{CDE} - (Q_{CDHM} + Q_{CDG})\alpha_{S1}} \quad (7.5)
\]
An uncorrected initial value for indicated compressible dynamic pressure is calculated as follows,

\[ Q_{cX} = P_{T1} + P_{S1} \]  (7.6)

The initial value for indicated compressible dynamic pressure is then adjusted for angle-of-attack effects per MDC memo 341-6241 dated "23Feb81".

\[ Q_{cS1} = Q_{cX} \{ 1 - (0.04 \{ \alpha \left[ \frac{55}{30} - 30 \} \})^2 \} \]  (7.7)

\[ QCIS1 = Q_{cS1} \]  (7.8)
Figure 7.5.e QCDE = f(Mach)
Figure 7.5.f QCDF = f(Mach)
Figure 7.5.g QCDE = f(Mach)
Figure 7.5.h QCDF = f(Mach)
8. ACTUATORS

The simulation described herein includes dynamic models for the following control surfaces,

(1) stabilators (right and left),
(2) rudders (right and left),
(3) ailerons (right and left),
(4) trailing-edge flaps (right and left),
(5) leading-edge flaps (right and left),
(6) speed brake, and
(7) thrust vectoring vanes (2 per engine, 4 total).

The stabilators, rudders, ailerons, trailing-edge, and leading-edge flaps are hydraulically powered and are referred to in both MDC documents and this report as the primary controls. The single speed brake is positioned between and forward of the vertical fins and is driven at a constant rate of 24 degrees per second. The lower and upper limits of the speed brake deflection are 0° and 60°. The primary controls and the speedbrake are found on the basic F/A-18 airframe.

The thrust vectoring vane actuation systems modeled in this simulation reflect a preliminary design of the thrust vectoring system installed on the F-18/HARV and do not agree with the final installation. The documentation of the final system will be undertaken in a separate report. The thrust vectoring vanes are each modeled as first order transfer functions with a steady state gain of 1, a time constant of (1/30) seconds, rate limits of 80 °/s and position limits of +/- 30°.

8.1 Linear Dynamics - Primary Controls

The actuation systems for the primary controls in their normal mode of operation are discussed in detail in pages 6-1 through 6-40 of MDC A7813, vol II. The servo loop block diagrams for the primary controls are given in figures 6-2, 6-4, 6-6, 6-8 and 6-10 of MDC A7813, vol II. These block diagrams are repeated in a simplified form in this document as figures 8.1 through 8.5. The high order models represented in these figures describe main ram response with external load.

The transfer functions for the five primary actuators (stabilator, rudder, aileron, leading-edge flaps, and trailing-edge flaps) are presented in Table 8.1 through 8.5. Each table contains three transfer function models of the corresponding actuator type; (a) a high order model; (b) an intermediate order model; and (c) a low order model. For each actuator type, transfer function (a) is derived from the high order block diagrams in figures 8.1 through 8.5. Transfer functions (b) are discussed in pages 6-18 through 6-24 of MDC A7813, vol II. The (b) transfer functions are second order for all except the stabilators, which are fourth order. Transfer functions (c) consists of the lowest order models, the first order transfer functions that are used in both the MDC simulation code and the DMS real-time simulation at LaRC. The (a) transfer functions can be realized by linearizing the nonlinear block diagrams of figures 8.1 to 8.5. Comparisons of gain and phase response of the (a), (b), and (c) transfer functions for the primary controls are shown in figures 8.6 through 8.10. The low order models agree pretty well in phase with the intermediate and high order models out to about 10 radians/second.

An initial form of the ACSL simulation included elastic dynamics (see section 1.2), and in that simulation the (b) transfer functions were implemented. When the elastic dynamics were removed and time histories were compared with results generated by the DMS simulation, significant differences in aircraft responses due to pilot pitch and yaw doublets resulted. These differences were much reduced when the stabilator and rudder actuator models were changed to the first order models. The ACSL simulation now uses the first order actuator models.
Figure 8.1. Stabilator Servoactuator Block Diagram

8.2 Nonlinearities - Primary Controls

The significant nonlinearities in the actuators include a minimum resolution in the digital command due to 12 bit digital-to-analog conversion, hydromechanical thresholds, rate limiting, and nonlinear gearing. The first three of these types of nonlinearities are given in Table 6.2.1-1 of MDC A7813, vol II, and are repeated in Table 8.6 below.

The main ram slewing rate limit is proportional to \((P_s - P_1)^{1/2}\), where \(P_s\) is the supply pressure (3000 PSI) and \(P_1\) is the pressure on the resisting side of the piston due to external load. The maximum slewing rate occurs when \(P_1\) is zero. When \(P_1\) equals \(P_s\), the actuator stalls.

In the ACSL simulation, of the possible nonlinear effects, only the no load rate limits are modeled. In both the MDC simulation and the DMS simulation, the no load rate limit used for the rudder actuators is 61 degrees/second instead of 56 degrees/second as shown in Table 8.6. Another set of specifications for actuator models can be found on page 12 of MDC report A8449 and is repeated below as Table 8.7. The no load rate limit for the rudder actuators is given as 61 degrees/second in Table 8.7. The 61 degree/second limit is used in the f18bas simulation.

81
For further discussion of gearing nonlinearities and plots of the effect of hinge moment on maximum actuator rate, the reader is referred to section 6.2 of MDC report A7813, vol II.

8.3 Speedbrace

The speedbrace system is described in section 8.7 of MDC A7813, vol I, Rev A. The speedbrace actuator is operated by a selector valve which ports hydraulic pressure to the main ram for extension or retraction. The selector valve is electrically controlled by a three position switch, OFF, RETRACT, and EXTEND, on the right hand throttle. The EXTEND position is a momentary. The OFF command holds the speedbrace in its current position. When the speedbrace is fully retracted, both "OFF" and "RETRACT" switch positions command the selector valve to the retract position.

The speedbrace rate is controlled by a flow regulator and restrictor. "The speedbrace extension time is limited to 2.5 seconds or approximately 20 degrees to 30 degrees per second (no load)" [MDC A7813, p8-14]. Maximum surface deflection is 60 degrees. In the f18bas simulation, the speedbrace no-load rate limit, SBNLRL, has been set to 60/2.5 = 24 °/s. No provision is made for reduced rate due to aerodynamic hinge moment. The maximum driving hinge moment available at 60 degrees open with the full 3000 psi of hydraulic pressure available is 296,000 in-lbs.

8.4 Thrust Vectoring Vane Actuators

The four actuators in the preliminary vane actuation system are each modeled with first order lag transfer functions with a time constant of 0.05 seconds, a rate limit of 80 °/sec, and position limits of +/- 30°. Again, this vane configuration of two vanes per nozzle is a preliminary version. The actual system implemented on the HARV F18 has three vanes per nozzle.
9. FLIGHT CONTROL SYSTEM (FCS)

The \textit{fl8bas} simulation implements the Control Augmentation System (CAS) of the inner loop of the F/A-18 Flight Control System defined by the 8.3.3 production programmable read-only memory (PROM) set. The theory of operation and design considerations of the CAS is described in section 9.1. The implementation issues associated with the \textit{fl8bas} simulation (as opposed to the actual aircraft) are discussed in section 9.2.

9.1 FCS Theory of Operation

The inner loop flight control law theory of operation for the F/A-18 is described in detail in section 16 of MDC report A7813, Vol I, rev A and section 1 of MDC report A4107, vol I, rev J. The inner loop control laws are divided into three channels: longitudinal, lateral, and directional. A preliminary thrust vectoring option (LTHVEC=.T.) exists in the code wherein additional pitch and yaw commands are generated by the control laws for use by the mixer/predictor. The mixer/predictor resolves the pitch and yaw command into actual vane commands for proposed thrust vectoring hardware. As indicated in section 1.2 of this report, the thrust vectoring option in the \textit{fl8bas} simulation represents a preliminary design version that has been superseded and will not be described in this document.

The inner loop CAS is a multi-rate digital controller. The actual flight computers update at a rate of 160 Hz. The inner loop calculations are performed at alternate frames of the flight control computer, so that the fastest inner loop of any of the controllers is 80 Hz. The details of the control law discretization can be found in MDC report A4107, vol I, rev J. All the sampling rates are fast enough that the continuous description offered here will suffice for analysis.

9.1.1 Longitudinal Auto Flap Up CAS

Three modes of leading-edge and trailing-edge flap management are performed in the pitch inner loop control laws of the F/A-18; (1) auto flap up (AFU), (2) half flaps, and (3) full flaps. The AFU mode is for up and away flight. The half and full flap settings are used in take-off and landing, respectively. In the \textit{fl8bas} simulation, only the auto flap up mode is supported. A block diagram of the pitch inner-loop control augmentation system in the AFU mode is presented in figure 9.1 (a-d). Figure 9.1 is a simplified version of "FIG 1/OFP V10.1" on page 1-13 of MDC report A4107, vol I, rev J. Paths in "FIG 1/OFP V10.1" having to do with outer loops, the direct electric link (DEL) reversion mode, and HALF and FULL flap management modes have been deleted. Also omitted from figure 9.1 are blocks defining stick dynamics, trim functions, and the g-limiter logic. The definition of the pitch gains (PKxx) in terms of pitch functions (FUNxx) are given in table 9.1. Table 9.2 defines the longitudinal filters used in figure 9.1. The pitch functions required to define quantities in both tables 9.1 and 9.2 are defined in figure 9.2 (a-o). The following quote is taken from pages 1-2 through 1-4 of MDC report A4107, Vol I, REV. J. Italics are comments inserted by the authors. Grammatical hyphens have been added.

Primary control of the F/A-18 aircraft longitudinal motions is accomplished through the CAS. The Direct Electric Link (DEL) and mechanical system provide backup for the pitch CAS. Management of the leading and trailing edge flaps is provided through the use of a cockpit switch which calls for either AUTO, HALF, or FULL flaps. A block diagram of the longitudinal control system is presented in Figure 1 (figure 9.1 of this document). Longitudinal functions and logic diagrams are given in Figure 1.1 through 1.44 (figure 9.2 of this document). Longitudinal digital filter characteristics are summarized in Table 1-1 (Table 9.2 of this document).
Auto Flap Up (CAS On) - The pitch CAS uses a pilot commanded longitudinal stick position input as a command to the CAS. The forward path gain is air data scheduled (Function 32A) to yield a uniform initial pitch acceleration response for sharp inputs. The CAS feedback parameters are a blend of air data scheduled pitch rate (Functions 40 and 68), normal acceleration, and angle of attack. Pitch rate and normal acceleration feedbacks give improved pitch dynamic characteristics and load factor control in the mid to high dynamic pressure portion of the flight envelope. Air combat maneuvering characteristics and increased stick-force-per-g cues in the low to mid dynamic pressure flight regime are provided by the air data scheduled pitch rate feedback. Angle-of-attack feedback provides additional increased stick force cues for low speed high angle-of-attack air combat maneuvering. Roll rate multiplied by yaw rate is fed to the longitudinal control system (Function 107) to reduce the effects of inertial coupling.

The pilot commanded stick position, pitch rate, normal acceleration, and angle-of-attack feedback signals are iterated at the rates shown in Figure 1 (figure 9.1 of this document).

The pitch CAS forward path is comprised of an air data scheduled gain (Function 32A), a forward loop integrator, and the stabilator servo and power cylinder. The aircraft response (feedback) is compared to the maneuver command; the resulting difference drives the servo/power cylinder to reduce the maneuver error to zero through the forward loop integrator. Consequently, the aircraft is automatically kept in steady state trim (hands off) since any aircraft normal acceleration different from the commanded normal acceleration is reduced to zero by the action of the integrator.

The notch structural filter located in the feedback paths attenuates any undesirable motions which are sensed by the motion sensors due to aeroelastic bending of the aircraft structure. The longitudinal forward loop gain (Functions 32A) and pitch rate feedback gains (Functions 40 and 68) are scheduled with air data. A supersonic (air data scheduled time constant, Function 22) lead-lag filter is employed in the pitch rate feedback path. The forward loop integrator gain is air data scheduled (Function 12) and angle-of-attack activated (AOA less than 33 degrees). This implementation is necessary to maintain adequate loop gain margins, phase margins, and handling qualities throughout the flight envelope. Scheduling pitch rate feedback gain with air data results in increased feedback gain with decreasing dynamic pressure or increasing altitude. This increases the stick force cues for mid to low speed flight conditions and provides a pitch attitude type of control law for tracking since pitch rate feedback is nulled via the forward loop integrator.

A speedbrake-to-stabilator interconnect (Function 100) is incorporated to alleviate g transients for speedbrake extension/retraction. The interconnect command is on/off in response to speedbrake solenoid valve command. The magnitude of the input command is air data scheduled. The interconnect command is lagged through a first order low-pass filter with the time constant scheduled with air data and as a function of speedbrake extension or retraction. The speedbrake extend time constant is less than the speedbrake retract time constant.

Flap Control - Auto Flap UP - With the flap switch in AUTO, the leading and trailing edge maneuvering flaps are scheduled with angle of attack and air data (Functions 24 and 27) to optimize performance, to improve the high angle of attack characteristics, and provide load alleviation at elevated g's. Flap position limits are computed as a function of air data inputs (Functions 25, 28 and 29) to prevent the application of excessive air loads on the flaps.

9.1.2 Lateral Auto Flap Up CAS

Figure 9.3 (a-d) is a simplified version of the diagram "Figure 2 / OFP V10.1" on page 1-69 of MDC report A4107, Vol 1, REV. J. Paths having to do with outer loops and the direct electric link (DEL) reversion mode have been deleted. The definition of the lateral gains (RKxx) in terms of roll functions (FUNxx) are given in Table 9.3. Table 9.4 defines the lateral filters used in figure 9.3. The roll functions required to define quantities in both tables 9.3 and 9.4 are defined in figure 9.4 (a-l). The following quote is from pages 1-65, 1-97 of MDC report A4107, Vol I, REV. J. Italics are comments inserted by the authors. Grammatical hyphens have been added.

Lateral control is accomplished by a control-by-wire system which commands the ailerons, differential stabilators, differential trailing-edge flaps, and differential leading-edge flaps. The controls consist of Control Augmentation System (CAS) and Digital and Analog Direct Electric Link (DEL) functions. A block diagram of the lateral control system is shown in Figure 2 (Figure 9.3 of this report). Lateral functions and logic diagram are presented in Figure 2.1 through 2.20 (Figure 9.4 of this report). Lateral digital filter characteristics are summarized in Table 1-3 (Table 9.4 of this report).

The roll CAS augments the pilot's roll stick inputs and provides roll damping through the aileron, differential stabilator, differential trailing-edge flaps, and differential leading-edge flaps. The center stick position command signal is summed with the roll rate feedback (p) to provide the closed loop control of the ailerons, differential stabilators, differential trailing-edge flaps, and differential leading-edge flaps. Because of the inherent high roll damping of the aircraft at low altitude high speed flight conditions, the roll rate feedback gain is reduced (gain scheduled) in this area. A limited authority roll rate feedback is used to improve trim stability in the area where the CAS roll rate feedback gain is reduced.

The control stick position sensor signal, after it is shaped by a parabolic gradient, provides the desired roll response of the augmented aircraft.

The roll CAS normal mode command path is comprised of an air data scheduled gain (Functions 4, 7, and 13). Function 4 is also the roll rate feedback gain schedule. The gain varies with dynamic and static pressure to provide acceptable loop stability and roll response characteristics throughout the envelope. Notch filters located in the roll rate feedback path attenuate motion sensor inputs due to aeroelastic bending of the aircraft structure. A notch filter is located in the stick position signal to prevent structural mode coupling through the stick position sensor. The frequencies are based on modes determined during Ground Vibration Testing. An additional fourth order roll-off filter is located in the feedback path to provide additional attenuation of the structural mode inputs and high frequency noise, the presence of which was detected during Iron Bird testing.

With wing stores, the roll rate feedback gain is increased for roll rates in excess of 110 degrees per second and the stick command gain (Function 13) is modified in order to limit the maximum roll rate to approximately 150 degrees per second. Without wing stores, the roll rate feedback gain is increased above 190 degrees per second to aid in limiting the maximum roll rate to approximately 220 degrees per second. (Wing stores are not an option in the f18bas simulation).

The maximum roll rate capability with or without stores is limited to 150 degrees per second above 5 g's normal load factor to reduce the vertical tail loads and reduce inertial coupling.
The aileron command gain is scheduled with angle of attack and air data (Functions 35 and 36). The angle-of-attack gain schedule eliminates excessive adverse sideslip during rolling maneuvers for high angles of attack at low dynamic pressure flight conditions. The air data gain schedule reduces the aileron command to zero at high dynamic pressure flight conditions where wing flexibility reverses the effective aileron aerodynamic moments. The air data schedule also avoids hinge moment limits. The aileron command is also limited by an angle of attack and air data schedule (Function 41) to optimize roll coordination.

The roll CAS signal which drives the differential stabilator is multiplied by a gain and then is limited by a gain schedule (Functions 6 and 101) and rate limited at 35 degrees per second to reduce the coupling between the roll and pitch axis at high dynamic pressure where the stabilator approaches hinge moment and bending moment limits. Stabilator bending moment alleviation is provided via a differential stabilator surface command gain scheduled with load factor (Function 101). The differential stabilator command is also limited by the stabilator pitch command (pitch priority) and by an angle-of-attack schedule (Function 41). The aileron and differential stabilator command signals also command rudder (for roll coordination) through the rolling surface-to-rudder interconnect (RSRI). The RSRI is gain scheduled with air data and angle of attack (Functions 30 and 38).

The differential trailing-edge flap command gain is scheduled with air data and angle of attack (Functions 31 and 34). The air data schedule permits the maximum differential deflection available without encountering hinge moment limiting or excessive vertical tail loads. The angle-of-attack schedule reduces the available deflection above 5 degrees AOA and eliminates it above 10 degrees AOA. Differential flaps are not necessary to meet roll performance requirements above these angles of attack.

The differential leading-edge flaps are gain scheduled with air data and load factor (Function 93) to provide improved roll rate in the low to mid altitude transonic speed range. The gain is reduced for increasing load factor, increasing altitude, and decreasing Mach in the transonic speed range.

Differential ailerons are used for active suppression of a wing stores aeroelastic oscillation. The forward sensor assembly lateral accelerometer signal is filtered to extract the oscillation component, which then drives the ailerons. The active suppression system is switched on by an air data schedule if the heavy wing stores discrete is set by the Mission Computer.

9.1.3 Directional Auto Flap Up CAS

Figure 9.5 (a-b) is a simplified version of the diagram "Figure 3 / OFP V10.1" on page 1-99 of MDC report A4107, Vol I, REV. J. Paths having to do with outer loops and the direct electric link (DEL) reversion mode have been deleted. The definition of the directional gains (YKxx) in terms of yaw functions (FUNxx) are given in Table 9.5. Table 9.6 defines the directional filters used in figure 9.5. The yaw functions required to define quantities in both tables 9.1 and 9.2 are defined in figure 9.6 (a-l). The following quote is from pages 1-93, 1-94 of MDC report A4107, Vol I, REV. J. Comments inserted by the authors are in italics. Grammatical hyphens have been added.

Directional control is accomplished by a control-by-wire (CBW) system which commands the twin rudders. The yaw CAS is the primary mode of operation with a DEL (Direct Electric Link) mode from the rudder pedal force transducers to the rudder actuators available for CAS off operation. A rolling surface-to-rudder interconnect (RSRI) is incorporated to minimize the sideslip accompanying roll maneuvers. The block diagram is shown in Figure 3 (Figure 9.5 of this document). Directional functions and logic diagrams are given in Figures 3.1 through 3.27 (Figure 9.6 of this document). Directional digital filters are summarized in Table 1-5 (Table 9.6 of this document).

The normal mode of control is closed loop employing stability axis yaw rate (r cos(\(\alpha\)) - p sin(\(\alpha\))) and lateral acceleration feedback control.

The rudder pedal force transducer signal, after it is shaped by a dead band followed by a parabolic gradient (Function 14), is air data scheduled (Function 10) to prevent a command which would exceed the vertical tail load limits. Air data and angle-of-attack gain schedules (Function 17 and 114) eliminate aircraft departures for full pedal inputs. Full surface authority is available at high angles of attack and low Mach numbers through the rudder pedal-to-rolling surface and rolling surface-to-rudder interconnects described below.

The CAS feedback loop contains a third order roll-off filter to attenuate high frequency noise and structural feedback modes. The computed stability axis yaw rate feedback signal is multiplied by a gain (Function 96) and then shaped by a washout network. The yaw rate (multiplied by cosine of angle of attack) feedback component is used to augment the Dutch roll damping. The remaining signal component, proportional to roll rate multiplied by the sine of angle of attack, is used to help provide sideslip reduction during high angle of attack maneuvering flight. Lateral acceleration feedback aids in reducing sideslip and provides turn coordination. The lateral acceleration and yaw rate feedback gains are air data scheduled (Functions 90 and 96) to increase directional stability at high altitude supersonic speeds and to optimize Dutch roll characteristics at low to mid altitude and speeds, respectively. Additional lateral acceleration air data and angle of attack gain schedules (Functions 112 and 113) improve directional stability above Mach 0.7 and 15 degrees angle of attack. Roll rate multiplied by pitch rate is fed to the directional control system to reduce the effects of inertial coupling (Function 108).

The forward loop consists of a gain scheduled with air data (Function 45). The gain reduces rudder pedal sensitivity in the high dynamic pressure region and optimizes the closed loop directional damping the roll coordination characteristics.

The rolling surface-to-rudder interconnect (RSRI) is used to control rudder deflections to minimize the sideslip accompanying roll maneuvers. The RSRI command is the total commanded differential aileron plus differential stabilator. The RSRI signal is passed through a lead-lag network and multiplied by variable gains, which are functions of angle...
of attack and air data (Functions 30 and 38). The RSR! allows coordinated rolls to be flown with the feet on the floor.

A rudder pedal-to-rolling surface interconnect is provided to reduce sideslip and angle of attack excursions due to rudder deflection at high angles of attack. The interconnect gain is scheduled with angles of attack and is scheduled to zero at low angles of attack (Function 39).

9.2. Flight Control System Implementation

The flight simulation flight control system (FCS) subroutines were created by starting with existing code which modeled flight controls in the Differential Maneuvering Simulator real-time F18 simulation (dmsf18). The code structure and variable nomenclature used in the dmsf18 simulation were left largely unchanged. The interface portions of the control subroutines were modified to be compatible with the Advanced Continuous Simulation Language (ACSL) structure. When calling FORTRAN subroutines from an ACSL simulation, arguments may be passed through a parameter list or through the global ACSL common block, ZZCOM. Using the global common block is risky because all the ACSL defined variables are in ZZCOM and duplicate names can easily exist in the called subroutine. In the interest of execution speed, real-time subroutines use a multiple common block structure to pass arguments instead of parameter lists. The existing real-time common blocks were replaced with parameter lists containing the feedback and driver values required by the FCS subroutines. Sensor and servoactuator models, which appeared in the real-time FCS subroutines, were removed and coded as continuous models in the ACSL main program. Minor modifications were required for the CDC FORTRAN V to VAX FORTRAN conversion. For example, multiple assignment statements can occur on a single line of code in CDC FORTRAN V (A=B=C), but not in VAX FORTRAN. Logical variables pertaining to real-time systems (i.e. the real-time monitor, cockpit lights, strip chart recorders, etc.) were removed. Library functions and subroutines were modified as required for compatibility. Extraneous code which was present for an alternate, expanded, flight control system was removed. A general cleanup of unused variables and dead end code was performed.

Five subroutines comprise the flight control loop. An executive routine, F18FCS, is called from the discrete block, FCS, in the main ACSL routine. The call is scheduled at a regular time interval specified by the ACSL variable, TSFCS. The default interval value is 1/40 (.025) second which represents a compromise between the various sampling rates of 80, 40, 20 and 10 samples per second used by the actual aircraft flight control computer. Sensor signals and pilot control positions are passed to the control routines through the subroutine call parameter list. Surface position commands are then computed and returned to the ACSL main routine through this parameter list. Figure 10.1 presents the overall flow of the executive routine and shows only the main driver and feedback values and the resulting surface deflections. Specific options and special conditions were not shown in this diagram to reduce the clutter. A complete list of passed parameters for subroutine F18FCS is given in tables 9.7 and 9.8.

The executive routine, F18FCS, computes logical variables indicating mode and filter coefficients. The mode logical variables are: spin mode, stores, the supermaneuver switch, automatic speedbrake retraction, and limiter override commands. The filter coefficients are for the dynamic pressure digital filters and the angle of attack signal digital filters. The remaining four control routines are called from F18FCS in the following order:

(1) the longitudinal control model, F18LONG,
(2) the lateral control model, F18LAT,
(3) the directional control model, F18DIR,
(4) and an auxiliary routine, F18AUX.

The basic inputs for the longitudinal axis control routine, F18LONG, are:

(1) the pilot longitudinal stick command,
(2) normal accelerometer feedback,
(3) pitch rate gyro feedback,
(4) angle-of-attack sensor feedback,
(5) dynamic pressure sensor scheduling input,
(6) and an aileron to stabilator interconnect command from the lateral control routine.
Figure 9.7. Implementation of the flight control laws
The basic outputs for the longitudinal axis control routine are:

1. stabilator surface commands,
2. the leading and trailing-edge flap commands,
3. and the symmetric thrust vectoring command.

The basic inputs for the lateral axis control routine, F18LAT, are:

1. the pilot lateral stick command,
2. roll rate sensor feedback,
3. normal accelerometers feedback,
4. lateral accelerometer feedback,
5. angle of attack sensor feedback,
6. dynamic pressure sensor scheduling input,
7. and a rudder to rolling surface crossfeed command from the directional routine.

The basic outputs for the lateral axis control routine are:

1. aileron surface commands,
2. the interconnect command to the stabilator and flaps,
3. and a rolling surface to rudder interconnect command.

The basic inputs for the directional axis control routine, F18DIR, are:

1. the pilot pedal command,
2. lateral accelerometer feedback,
3. roll rate gyro feedback,
4. yaw rate gyro feedback,
5. angle of attack sensor feedback,
6. and a rolling surface to rudder interconnect command from the lateral routine.

The basic outputs for the directional axis control routine are:

1. differential rudder command,
2. symmetric rudder command,
3. and a differential thrust vectoring command.

The auxiliary routine blends and schedules the thrust vectoring commands and transforms symmetric and differential surface commands into left and right specific surface commands. The auxiliary routine originally contained servoactuator and hinge moment models. Hinge moments were not being computed at the time of this documentation and the servoactuators existed in the continuous portion of the simulation.

The call to the F18 flight control system subroutine (F18FCS) appears twice in the main ACSL program (f18bas). A flowchart of the main program which illustrates the trimming and main program loops is shown in figures 2.2 through 2.4 in section 2 of this report.

The call to subroutine F18FCS in the initial...end code section of the simulation (figure 2.3) is required by the trimming procedure. F18FCS is only called if the "FCS engaged" logical (LFCS) is true. The call to F18FCS in initial...end code block is required because the ACSL translator sorts the FCS discrete block and places it after the derivative section where it is can then be checked for an event crossing, (T=TFCS in this case). Actuator models represent physical systems (the servoactuator motors that drive the aircraft surfaces) and appear in the continuous
(derivative) portion of the program code. If the call to F18FCS were not present in the initial section of the ACSL program, the following sequence would occur:

(a) The trim routine would drive a pilot input.
(b) Actuator responses would be computed before the discrete flight control system call.
(c) The surface control command from the previous loop would drive the actuator.
(d) No surface deflection response to the trial pilot input would be computed.
(e) A singularity error would be noted in the trim routine.
(f) 'ESTIMATED [A] MATRIX SINGULAR' would be returned at ACSL prompt.
(g) The simulation would remain untrimmed.

As a result of entering the ACSL runtime command 'START', the simulation process begins execution at the top of the initial section. The top portion of the initial section code is executed once at the beginning of each run (i.e., each time START is entered at the ACSL prompt) and is composed primarily of type declarations (LOGICAL, INTEGER) and constant statements. Constant statements are implemented by the ACSL translator as Fortran DATA statements and the values are entered once into the computer memory when the program is linked. A few direct assignment statements, notably ITFLG=1, also occur in top portion of the initial section code and these values are reset with each run. The continuation statement, 1100..CONTINUE, marks the top of the trim loop. Code appearing after this continuation statement is executed with each loop of the trim sequence until the pass on which the variable ITFLG > 2 is true. Successful trim is indicated by IRFLG=3. The subroutine INITD is called following the !100 statement. This call was included to clear the event list and prevent problems with the crossing value setting of the afterburner switch discrete. Initial values for sensor data are computed prior to the initial flight control system call. The first call to the flight control system computes surface deflection commands based on the initial trim values of pilot control commands. These initial trim pilot control values are read on the first pass through the initial section by the subroutine LOAD from the trim data file 'FI8TR'. The trial pilot control values are used to compute trim are:

(a) longitudinal stick position, PCSTR (Pilot Control Stabilator Trim),
(b) lateral stick position, PCATR, (Pilot Control Aileron Trim),
(c) and pedal force, PCRTR (Pilot Control Rudder Trim)

The logical variable LFCS must be set true for the flight control system to be called. A false value of LFCS will cause the flight control system to be bypassed. The LFCS false condition is present to enable the simulation to be run from direct surface deflection commands. Trim is achieved when the first NXTR elements of the XTRIM array (see table 2.1 in section 2.) are driven to values that cause first NXTR elements of the YTRIM array (table 2.2) to be zero to within some tolerance. The specific combination of XTRIM values used to achieve trim is dependent on which type of trim condition is required (a straight and level trim should not require pedal and lateral stick adjustment, unless some asymmetry was introduced to the aerodynamics). This combination is set up in the trim condition file ('FI8TR'). The procedure for setting up a trim case is more fully described in the section 2.2 of this report.
10. CONCLUSION

A mathematical model and associated computer program (fl8bas) to simulate a twin-tailed high performance fighter airplane (McDonnell Douglas F/A-18) were described. The simulation was intended to support advanced control law research for application to high performance aircraft. The modeled flight envelope is extensive, allowing investigations in the high-angle-of-attack portion of the flight regime. While no comparisons with F/A-18 flight data are offered, the simulation is sufficiently detailed to support proof-of-concept studies.

The simulation program was written in the Advanced Continuous Simulation Language (ACSL). Wherever possible, continuous system dynamics were modeled in the DERIVATIVE portion of the ACSL program structure. This policy allows important features of ACSL, such as the automatic generation of linear models and error checking on the numerical integration process, to be utilized. Furthermore, ACSL, by implementing continuous and discrete event dynamics via the DERIVATIVE and DISCRETE block conventions, allows a coherent implementation of multirate digital control laws that should not be lightly discarded.

The simulation math model includes the nonlinear, six degree-of-freedom rigid-body equations, an engine model, sensors, and first-order actuators with rate and position limiting. A simplified form of the F/A-18 digital control laws (version 8.3.3) is implemented, including only the Auto Flap Up (AFU) flight mode used for air combat maneuvering. Aerodynamic forces and moments are calculated from a wind-tunnel-derived database using table look-ups with linear interpolation. The aerodynamic database has an angle-of-attack range of -10° to +90° and a sideslip range of -20° to +20°. The effects of elastic deformation were incorporated in a quasi-static-elastic manner. Elastic degrees of freedom are not actively simulated. In the engine model, the throttle-commanded steady-state thrust level and the dynamic response characteristics of the engine are based on airflow rate as determined from a table look-up. Afterburner dynamics are switched in at a threshold based on the engine airflow and throttle position.

The source code can be obtained from the authors.

\[ \Delta C_{m\delta_{AR}} \] increment in pitch coefficient due to right aileron, rigid airplane, \( \text{deg}^{-1}, f(\alpha, \delta_{AR}, M) \)
\[ \Delta C_{m\delta_{HL}} \] increment in pitch coefficient due to left stabilator position, rigid airplane, \( f(\alpha, \delta_{HL}, M) \)
\( \Delta C_m \delta_{HR} \) increment in pitch coefficient due to right stabilator position, rigid airplane, \( f(\alpha, \delta_{HR}, M) \)  
\( \Delta C_m \delta_{LG} \) increment to pitch coefficient for fully deployed landing gear, \( f(\alpha) \)  
\( \Delta C_m \delta_{R} \) increment in pitch coefficient due to antisymmetric rudder, \( f(\alpha, |\delta_R|, M) \)  
\( \Delta C_m \delta_{RT} \) increment in pitch coefficient due to symmetric rudder (rudder toe-in), \( f(\alpha, \delta_{RT}, \delta_{f/A}) \)  
\( \Delta C_m \delta_{SB} \) increment to pitch coefficient for full 60 degree deflection in speed brakes, \( f(\alpha, M) \)  
\( \Delta C_n^F \) increment to \( C_n^r \) due to elastic deformation, \( f(M, H_p) \)  
\( \Delta C_n^F \) increment to \( C_n^\beta \) due to elastic deformation, \( f(M, H_p) \)  
\( \Delta C_n \delta_{AL} \) increment in yaw coefficient due to left aileron position, rigid airplane, \( f(\alpha, \delta_{AL}, M) \)  
\( \Delta C_n \delta_{AR} \) increment in yaw coefficient due to right aileron position, rigid airplane, \( f(\alpha, \delta_{AR}, M) \)  
\( \Delta C_n \delta_f \) increment in yaw coefficient for full 20 degree deployment of symmetric trailing-edge flaps, rigid airplane, used with sign of \( \beta \), \( f(|\beta|, \alpha, M) \)  
\( \Delta C_n \delta_n \) increment in yaw coefficient for full 25 degree deployment of symmetric leading-edge flaps, rigid airplane, used with sign of \( \beta \), \( f(|\beta|, \alpha, M) \)
\[ \Delta C_n \delta_R \] increment in yaw coefficient due to antisymmetric rudder, rigid airplane, used with sign of \( \delta_R \), \( f(\alpha, |\delta_R|, M) \)

\[ \Delta C_n \delta_{SB} \] increment to yaw coefficient for full 60 degree deflection in speed brakes per degree of sideslip, deg\(^{-1}\), \( f(\alpha, |\beta|, M) \)

\[ \Delta C_Y^F \] increment to \( C_Y \) due to elastic deformation, \( f(M, H_\rho) \)

\[ \Delta C_Y^F \] increment to \( C_Y^\beta \) due to elastic deformation, \( f(M, H_\rho) \)

\[ \Delta C_Y^\delta_{AL} \] increment in side force coefficient due to left aileron position, rigid airplane, \( f(\alpha, \delta_{AL}, M) \)

\[ \Delta C_Y^\delta_{AR} \] increment in side force coefficient due to right aileron position, rigid airplane, \( f(\alpha, \delta_{AR}, M) \)

\[ \Delta C_Y^\delta_f \] increment in side force coefficient for full 20 degree deployment of symmetric trailing-edge flaps, rigid airplane, used with sign of \( \beta \), \( f(|\beta|, \alpha, M) \)

\[ \Delta C_Y^\delta_n \] increment in side force coefficient for full 25 degree deployment of symmetric leading-edge flaps, rigid airplane, used with sign of \( \beta \), \( f(|\beta|, \alpha, M) \)

\[ \Delta C_Y^\delta_R \] increment in side force coefficient due to antisymmetric rudder, rigid airplane, used with sign of \( \delta_R \), \( f(\alpha, |\delta_R|, M) \)

\[ \Delta C_Y^\delta_{SB} \] increment to side force coefficient for full 60 degree deflection in speed brakes per degree of sideslip, deg\(^{-1}\), \( f(\alpha, |\beta|, M) \)

\[ \theta \] pitch angle, radians

\[ \rho \] density of the air, slugs/ft\(^3\)

\[ \phi \] roll angle, radians
\[ \Psi \] yaw angle, radians

\[ \Psi_{\text{engL}} \] left engine cant angle in x-y plane, pos nose right, \((-1.98^\circ)\)

\[ \Psi_{\text{engR}} \] right engine cant angle in x-y plane, pos nose right, \((1.98^\circ)\)

**Subscripts**

- \( a \): aerodynamic, with respect to the air mass
- \( A \): due to air loads
- \( \text{asm} \): due to asymmetries
- \( \text{E,eng} \): engine induced
- \( G \): due to gravity
- \( \text{rf} \): quantity computed at the aerodynamic reference center (a.r.c.)
- \( \text{wg} \): component due to winds, turbulence, or gust
- \( x \): component along the \( X_B \) (body frame) axis
- \( y \): component along the \( Y_B \) (body frame) axis
- \( z \): component along the \( Z_B \) (body frame) axis

**Notation**

- \( \{ \} \): column vector
- \( [\cdot] \): matrix or row vector
- \( [\cdot]^\prime \): transpose of \([\cdot]\)
- \( x_{1}^{a}_{b} \): the variable \( x \) restricted to the range, \( b \leq x \leq a \), typically used to describe a function argument that is limited.

**Acronyms**

- **ACSL**: Advanced Continuous Simulation Language
- **AFU**: Auto-Flap Up mode of the F/A-18 Flight Control System (8.3.3 PROM)
- **AGCB**: Aircraft Guidance and Controls Branch at NASA LaRC

APPENDIX A - SIMULATION VARIABLES

Simulation Variable Naming Plan

Development of the simulation model involved the efforts of several engineers and programmers and has included receipt of data, documentation, and several Fortran subroutines from MDC and other sources. This effort has given the authors a keen sense of the desirability of a "standard" variable nomenclature for coding simulation models. Without a "standard" variable nomenclature, it was generally impossible to follow the coded logic without having the documentation in hand. This section describes our efforts at maintaining a consistent variable naming strategy. The creation of meaningful variable names was made challenging by the restriction in ACSL version 9 to six character variable names. ACSL version 10 supports longer variable names.

The authors developed a system for naming variables. This should not be confused with issuing a variable dictionary for project personnel to use. The philosophy behind the variable nomenclature system was that any given variable name could be constructed from a set of predefined mnemonics (base names; prefix and suffix modifiers), given an appropriate set of construction rules. This philosophy is based upon ideas enunciated by Mitchell and documented in Arbuckle (1987). A set of mnemonics developed by the authors is listed in tables A.1 through A.3. The construction rules for creating a variable name are as follows:

1) In keeping with the ANSI Fortran 77 standard and the requirements of ACSL, all variable names are six characters or less.
2) Prefix and suffix modifiers may only be used in combination with a base name.
3) Multiple prefixes may only be used if their nesting levels are different. The highest nesting level prefix will be leftmost, followed by the base name.
4) Multiple suffixes may only be used if their nesting levels are different. The highest nesting level suffix will be rightmost.
5) Base name truncation may be used to meet the requirement that all names be six characters or less. If truncation is required, remove the right character of the base name.

As an example of using the nomenclature system and construction rules, consider a variable defining $\beta$ in units of degrees at the aerodynamic reference point. The base name for $\beta$ is BET, the suffixes are DG and RF, respectively. The suffix DG has a nesting level of two, and the suffix RF has a nesting level of three (see table A.3). Constructing the variable name using rule number five results in BETDGRF, which is a seven-character name and violates rule number one. Using rule number six, remove the right character of BET to give us BEDGRF as the variable name which satisfies the construction rules.

When simulation model components were derived from preexisting code, the authors were reluctant to totally discard the variable name structure already in place. Not all of the variable names in the simulation were constructed according to the rules of this section.

Simulation Dictionary Option

ACSL provides for maintaining a simulation dictionary. If the logical LVDEF in the simulation is set true at run time, a call to LISTD(29) is made in the terminal block of the translator source code. Calling LISTD(29) causes a list of variable names and definitions to be read from unit 29 and written to the "PRN" output unit along with the values of all the variables in the simulation [ACSL (1987)]. All variables and their values are listed on the "PRN" output unit. The variables not found on the dictionary (unit 29) are simply listed without definitions. The ACSL executive program is not aware of any variables internal to called Fortran subroutines.
List of Simulation Variables

A81  left engine nozzle exit area, in²
A82  right engine nozzle exit area, in²
ABL  marker for left afterburner "state update" discrete block
ABLLL left engine afterburner thrust lower rate limit, lbs/sec
ABLLR right engine afterburner thrust lower rate limit, lbs/sec
ABR  marker for right afterburner "state-update" discrete block
ABSWL .true. if left engine afterburner is activated
ABSWR .true. if right engine afterburner is activated
ABULL left engine afterburner thrust upper rate limit, lbs/sec
ABULR right engine afterburner thrust upper rate limit, lbs/sec
ALDGRF angle of attack at the aerodynamic reference center (a.r.c.), degrees
ALF  angle of attack at the c.g., radians
ALFB  air data probe local angle-of-attack bias
ALFD  d/dt of ALF, rad/sec
ALFDP  angle of attack at the c.g., degrees
ALFDP  d/dt of ALFP, degree/sec
ALFLM limited angle of attack, used in Pitot tube sensor model, degrees
ALFP  air data probe angle of attack, degrees
ALFPIC air data probe angle-of-attack initial condition, degrees
ALFS  sensed angle of attack, equal to ALFS0 or ALFS1 based ISENS = 0 or 1
ALFS0 actual or true angle of attack, equal to ALFDG, degrees
ALFS1 output of air data models, degrees
ALFTR angle of attack required for trim, radians
AX  acceleration in x-body direction, g's
AY  acceleration in y-body direction, g's
AYS  sensed lateral acceleration, AV, equal to AYS0 or AYS1 based on ISENS = 0 or 1, g's
AYS0 true lateral acceleration, = AV, g's
AYS1 output of lateral accelerometer sensor model, g's
AYW  wind axis lateral acceleration, ft/sec²
AZ  acceleration in z-body direction, g's
AZEL azimuth angle of left engine as installed, 1.98 degrees
AZER azimuth angle of right engine as installed, 1.98 degrees
AZS  sensed normal acceleration, equal to AZS0 or AZS1 based on ISENS, g's
AZS0 true normal acceleration, equal to AZ, g's
AZS1 output of normal accelerometer sensor model, g's
AZW  wind axis normal acceleration, ft/sec²
BEDGRF sideslip angle at the aerodynamic reference center (a.r.c.), degrees
BET  sideslip angle at the c.g., radians
BETD  d/dt of BET, rad/sec
BETDG sideslip angle at the c.g., degrees
BETTR value of BET required for trim, calculated in trim search, radians
BLCG buttck line coordinate of the center of gravity, inches
BLENGL buttck line coordinate of the engine/airframe interface, left engine, -18.9 in.
BLENGR buttck line coordinate of the engine/airframe interface, right engine, 18.9 in.
BLRF buttck line coordinate of the aerodynamic reference center, 0.00 inches
BWRF reference wing span used for nondimensional aero coefficients, 37.42 ft
C1RFSF total steady-flow span used for nondimensional aero coefficients, 37.42 ft
C1ASLN commanded antisymmetric aileron, linearization input only, degrees
CAASP dynamic check perturbation signal to antisymmetric aileron command, degrees
CAL commanded left aileron, degrees
CAR commanded right aileron, degrees
commanded antisymmetric aileron, linearization input only, degrees

dynamic check perturbation signal to symmetric aileron command, degrees

left power lever angle command from auto throttle, degrees

right power lever angle command from auto throttle, degrees

drag coefficient at aerodynamic reference center, steady flow ( $\alpha = 0$ ), n.d.

commanded antisymmetric trailing-edge flap, linearization input only, degrees

dynamic check perturbation signal to antisymmetric trailing-edge flap command, degrees

command to left trailing-edge flap actuator, degrees

command to right trailing-edge flap actuator, degrees

commanded symmetric trailing-edge flap, linearization input only, degrees

dynamic check perturbation signal to symmetric trailing-edge flap command, degrees

simulation communication interval, time interval at which data is written to the master time history file or available at the screen, seconds

lift coefficient at aerodynamic reference center, steady flow ( $\alpha = 0$ ), n.d.

Target trim value for CLRFSF if "12" is in active part of IYSEL array.

pitch (about y-body axis) coefficient at aerodynamic reference point, steady flow ( $\alpha = 0$ ), n.d.

commanded antisymmetric leading-edge flap, linearization input only, degrees

dynamic check perturbation signal to antisymmetric leading-edge flap command, degrees

command to left leading-edge flap actuator, degrees

command to right leading-edge flap actuator, degrees

eyaw (about z-body axis) coefficient at aerodynamic reference point, steady flow ( $\alpha = 0$ ), n.d.

commanded symmetric leading-edge flap, linearization input only, degrees

dynamic check perturbation signal to symmetric leading-edge flap command, degrees

intermediate quantity, $\frac{c}{2V}$, sec

commanded antisymmetric power lever angle, linearization input only, degrees

dynamic check perturbation signal to antisymmetric power lever angle command, degrees

left power lever angle command from the pilot, degrees

left power lever angle command from the pilot required to for trim, degrees

right power lever angle command from the pilot, degrees

right power lever angle command from the pilot required to for trim, degrees

commanded symmetric power lever angle, linearization input only, degrees

dynamic check perturbation signal to symmetric power lever angle command, degrees

commanded symmetric power lever angle, signal array used in IDYNCK=3 option wherein an arbitrary input stream can be constructed

commanded antisymmetric rudder (both t.e.left), linearization input only, degrees

dynamic check perturbation signal to antisymmetric rudder, degrees

command to left rudder actuator, degrees

command to right rudder actuator, degrees

commanded symmetric rudder, linearization input only, degrees

dynamic check perturbation signal to symmetric rudder command, degrees

cosine of angle of attack at the c.g., $\cos(\alpha)$

component of total right leading-edge flap deflection, linearization input only, degrees
= DNRLN (if not.LLNCSY) or (DNSYLN + DNASLN) (if LLNCSY).
symmetric leading-edge flap deflection, degrees
component of total symmetric leading-edge flap deflection, linearization input only, degrees
symmetric leading-edge flap deflection resulting from trim calculations, degrees
component of total antisymmetric power lever angle input, linearization only, degrees
antisymmetric power lever angle deflection resulting from trim calculations, degrees
d/dt of left throttle boost output signal, degrees/sec
d/dt of right throttle boost output signal, degrees/sec
left throttle boost output signal, degrees
left throttle boost output signal initial condition, degrees
added to DPPL, linearization input only, degrees
= DPLLN (if .not.LLNCSY) or (DPSYLN - DPASLN) (if LLNCSY).
right throttle boost output signal, degrees
right throttle boost output signal initial condition, degrees
added to DPPL, linearization input only, degrees
= DPRLN (if .not.LLNCSY) or (DPSYLN + DPASLN) (if LLNCSY).
component of total symmetric throttle boost output signal, linearization input only, degrees
symmetric power lever angle deflection resulting from trim calculations, degrees
position output of left rudder actuator, degrees
position output of right rudder actuator, degrees
antisymmetric rudder deflection, both t.e. left, degrees
component of total antisymmetric rudder deflection, linearization input only, degrees
antisymmetric rudder deflection resulting from trim calculations, degrees
d/dt of left rudder, degrees/sec
d/dt of right rudder, degrees/sec
total left rudder position (pos t.e.left), includes linearization input, degrees
left rudder deflection initial condition, degrees
= DRLLN (if .not.LLNCSY) or (DRSYLN - DRASLN) (if LLNCSY).
total right rudder position (pos t.e.left), includes linearization input, degrees
right rudder deflection initial condition, degrees
= DRRLN (if .not.LLNCSY) or (DRSYLN + DRASLN) (if LLNCSY).
symmetric rudder deflection, both t.e. in, degrees
component of total symmetric rudder deflection, linearization input only, degrees
symmetric rudder deflection resulting from trim calculations, degrees
position output of left stabalator actuator, degrees
position output of right stabalator actuator, degrees
antisymmetric stabalator deflection, degrees
component of total antisymmetric stabalator deflection, linearization input only, degrees
antisymmetric stabalator deflection resulting from trim calculations, degrees
d/dt DSB, degrees/sec
initial condition for DSB, degrees
component of total speed brake deflection, linearization input only, degrees
d/dt of left stabalator, degrees/sec
d/dt of right stabalator, degrees/sec
total left stabalator position, includes linearization input, degrees
left stabalator deflection initial condition, degrees
component of total left stabalator deflection, linearization input only, degrees
DSLLN1 = DSLLN (if .not.LLNCSY) or (DSSYLN - DSASLN) (if LLNCSY).
DSR  total right stabilator position, includes linearization input, degrees
DSRIC right stabilator deflection initial condition, degrees
DSRLN component of total right stabilator deflection, linearization input only, degrees
DSRLN1 = DSRLN (if .not.LLNCSY) or (DSSYLN + DSASLN) (if LLNCSY).
DSSY  symmetric stabilator deflection, degrees
DSSYLN component of total symmetric stabilator deflection, linearization input only, degrees
DSSYTR symmetric stabilator deflection resulting from trim calculations, degrees
DSTMBT pilot stick pitch trim button
DTVOLL lower left thrust vectoring vane deflection, actuator output, degrees
DTV0LU upper left thrust vectoring vane deflection, actuator output, degrees
DTV0RL lower right thrust vectoring vane deflection, actuator output, degrees
DTV0RU upper right thrust vectoring vane deflection, actuator output, degrees
DTVDLL d/dt of lower left thrust vectoring vane deflection, degrees/sec
DTVDLU d/dt of upper left thrust vectoring vane deflection, degrees/sec
DTVDRRL d/dt of lower right thrust vectoring vane deflection, degrees/sec
DTVDRU d/dt of upper right thrust vectoring vane deflection, degrees/sec
DTVLL total left engine thrust vectoring vane deflection, degrees
DTVLLN left lower thrust vectoring vane deflection, linearization input only, degrees
DTVLLU left upper thrust vectoring vane deflection, degrees
DTVRL total left engine thrust vectoring vane deflection, degrees
DTVRLN right lower thrust vectoring vane deflection, degrees
DTVRLN added to total right engine thrust vectoring vane deflection, linearization input only, degrees
DTVRU right upper thrust vectoring vane deflection, degrees
DX1 intermediate variable in pressure sensor function calculations
DX2 intermediate variable in pressure sensor function calculations
E0   quaternion, n.d.
E00  E0 prior to normalization
E000 Direct integral of E0D = d/dt E0
E02  E0**2, used in direction cosine calculations
E0D  d/dt of E0, = .5*(-E1*P-E2*Q-E3*R), rad/sec
E0IC Initial condition for E0, derived from trim Euler angles
E1   quaternion, n.d.
E10  E1 prior to normalization
E100 Direct integral of E1D = d/dt E1
E12  E1**2, used in direction cosine calculations
E1D  d/dt of E1, = .5*(E0*P-E3*Q+E2*R), rad/sec
E1IC Initial condition for E1, derived from trim Euler angles
E2   quaternion, n.d.
E20  E2 prior to normalization
E200 Direct integral of E2D = d/dt E2
E22  E2**2, used in direction cosine calculations
E2D  d/dt of E2, = .5*(E3*P+E0*Q-E1*R), rad/sec
E2IC Initial condition for E2, derived from trim Euler angles
E3   quaternion, n.d.
E30  E3 prior to normalization
E300 Direct integral of E3D = d/dt E3
E32  E3**2, used in direction cosine calculations
E3D  d/dt of E3, = .5*(-E2*P+E1*Q+E0*R), rad/sec
E3IC initial condition for E3, derived from trim Euler angles

A.9
used to prevent divide by zero, $10^{-10}$

time at which dynamic check perturbation is applied, sec

FCS logical for lateral gain schedule bypass, default = .F., (DO NOT CHANGE)

FCS logical to reset lateral trim integrator, default = .F., (DO NOT CHANGE)

marker for flight control system discrete block

FCS logical for pitch forward loop gain (8.3.3 PROM set), default = .T., (DO NOT CHANGE)

= Mach number, but limited so that: $0.9 \leq \text{FGKAOA} \leq 1.4$. Used as independent variable for sensor angle-of-attack gain value look-up.

gross force produced by left engine prior to inclusion of thrust vectoring effects, lbs.

gross force produced by right engine prior to inclusion of thrust vectoring effects, lbs.

left engine thrust vectoring vane deflection angle, degrees

right engine thrust vectoring vane deflection angle, degrees

= Mach number, but limited so that: $0.0 \leq \text{FHM1} \leq 1.65$. Used as independent variable in static pressure sensor look-up.

left engine ram drag, lbs

right engine ram drag, lbs

fuselage station coordinate of the center of gravity, inches

fuselage station coordinate of the engine/airframe interface, either engine, 687.5 in.

fuselage station coordinate of the aerodynamic reference center, inches

event marker for flight test data control input discrete block

array used to hold 1 record of flight data read off a file, 50 elements.

total generalized force vector for rigid-body dynamics

aerodynamic component of FVR

thrust induced component of FVR

gravity induced component of FVR

inertial component of FVR

aerodynamic disturbance (wind and gust) component of FVR

acceleration due to gravity, 31.174 ft/sec$^2$

longitudinal flight path angle, radians

longitudinal flight path angle, degrees

target longitudinal flight path angle used in trim search, radians

GAM - GAMTR, driven to zero by trim search

candidate to prevent one component of the solution vector from reaching a solution earlier and remaining fixed. An unchanging element of solution vector will lead to a singularity in the sensitivity matrix estimation.

l/g, used to scale various variables

gain on left engine thrust error, VAC.

gain on right engine thrust error, VAC.

gain on left engine core dynamics. Second order filter.

gain on right engine core dynamics. Second order filter.

angle-of-attack sensor gain value.

FCS logical used in g-limit on stick input, default = .T. (DO NOT CHANGE)

desired load factor used in trim search when TCASE=3, g's

FCS logical used for g load override (TK5, TK8), default = .F. (DO NOT CHANGE)

vertical distance from sea level to aircraft c.g., ft

d/dt of H, ft/sec

vertical distance from ground to the a.r.c., ft.
HIC  initial condition for $H, \text{ ft}$
HRF  1962 standard atmosphere altitude in feet corresponding to a given air density, $\rho$, in slugs/ft$^3$
HSTORE FCS logical for heavy stores, default = .F. (DO NOT CHANGE)
I  summing index used throughout simulation
IALG integer switch to select ACSL integration algorithm:
(1) Adams-Moulton, variable step, variable order
(2) Gear's stiff; variable step, variable order
(3) Runge-Kutta 1$^{st}$ order or Euler
(4) Runge-Kutta 2$^{nd}$ order (default for this simulation)
(5) Runge-Kutta 4$^{th}$ order (default for ACSL)
(6) User supplied subroutine (INTEG)
(7) Runge-Kutta-Fehlberg 2$^{nd}$ order
(8) Runge-Kutta-Fehlberg, 5$^{th}$ order
IDYNCK  Integer switch used to invoke dynamic check capability
(0) No disturbance input
(1) One sided pulse
(2) Doublet
(3) User defined signal, read from array SIG
II  index used for sensor data tables
IN2FT  conversion factor, 1/12 (ft/in)
ISENS  FCS flag for sensor model
(0) sensor effects off, ideal measurements
(1) MDC sensor model (default)
ITFLG integer switch used to control program flow when trimming
ITR loop count used in inner loop of trim search. When a new candidate solution vector is calculated, the resulting derivatives are then calculated ITRMX times. This allows implicit loops in the trim loop to settle out. Implicit loops are caused by the fact that accelerations are inputs the control system that determine control surface position. An alternate way to break the loop would be to include actuator states in the trim vector. The trim search works best when the trim vector is kept small.
ITRMX number of passes made through equations of motion in inner trim loop. See ITR. Default = 6.
IXSEL integer pointer array of size NXTRMX used to select elements of trim solution vector, XTRIM. The first NXTR elements of IXSEL select from 29 possible independent variables. XTRIM is formed in subroutine XFORM.
IXX aircraft moment of inertia about x-body axis, slug-ft$^2$
IXZ aircraft xz cross product of inertia, slug-ft$^2$
IYSEL integer pointer array of size NXTRMX used to select elements to drive to zero in the trim output vector, YTRIM. The first NYTR elements of IYSEL select from 15 possible output variables. YTRIM is formed in subroutine YFORM.
IYY aircraft moment of inertia about y-body axis, slug-ft$^2$
IZZ aircraft moment of inertia about z-body axis, slug-ft$^2$
J simulation summing index
KFS longitudinal stick force spring, = 7.0 lbs/in, input to F18FCS
LAMDA difference between ground track angle and heading angle, radians
LCAASP logical switch (.T.) A dynamic check perturbation is added to the antisymmetric aileron command.
(.F.) no action (default)
LCASYP logical switch

A.11
A dynamic check perturbation is added to the symmetric aileron command.  

**LCFASP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the antisymmetric trailing-edge flap command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric trailing-edge flap command.  

**LCFSYP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the symmetric trailing-edge flap command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the antisymmetric leading-edge flap command.  

**LCNASP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the antisymmetric leading-edge flap command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric leading-edge flap command.  

**LCNSYP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the symmetric leading-edge flap command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the antisymmetric power lever angle command.  

**LCPASP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the antisymmetric power lever angle command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric power lever angle command.  

**LCPSYP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the symmetric power lever angle command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the antisymmetric rudder command.  

**LCRASP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the antisymmetric rudder command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric rudder command.  

**LCRSYP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the symmetric rudder command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the antisymmetric stabilator command.  

**LCSASP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the antisymmetric stabilator command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric stabilator command.  

**LCSBP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the speed brake command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the symmetric stabilator command.  

**LCSSYP**  
logical switch  
(\text{T.}) A dynamic check perturbation is added to the symmetric stabilator command.  
(\text{F.}) no action (default)

A dynamic check perturbation is added to the antisymmetric stabilator command.  

**LDBA**  
logical switch - used for debugging aerodynamic calculations.  
(\text{T.}) Extended debugging output is written to unit PRN for each call to the aerodynamic coefficient calculations.  
(\text{F.}) no action (default)

**LDBMI**  
logical switch - used for inertial effects calculation debugging.  
(\text{T.}) Extended debugging output is written to unit PRN for each calculation of the inertial components of the generalized force vector and mass matrix.  
(\text{F.}) no action (default)

**LDBOUT**  
logical switch - primary simulation debugging logical
(.T.) Extended ACSL debugging output is written to unit PRN after the trim search or when time reaches TSTP.

(.F.) no action (default)

LDBSS logical switch - debugging logical for the subroutine that calculates the accelerations by solving the vector equation [M][a] = {f}

(.T.) Debugging output is written to unit PRN from subroutine XRBVDC.

(.F.) no action (default)

LDBTR logical switch - used for debugging failed trim attempts.

(.T.) Each new solution trial, XTRIM, and the resulting YTRIM vector are written to unit=6 (typically the screen) and also unit=PRN

(.F.) no action (default)

LEULER logical switch:

(.T.) Euler angles rates are integrated directly.

(.F.) quaternion derivatives are integrated. (default)

LFCS logical switch - enables flight control system - read in from file "f18tr.dat"

(.T.) FCS on (default)

(.F.) FCS off

LFTD logical switch - enables use of flight data to drive control surface deflections

(.T.) Control deflections set to data in FTDAT. Actuators bypassed.

(.F.) Normal simulation operation. (default)

LLDTR logical switch

(.T.) When START command is executed, initial conditions for all possible XTRIM variables are read in from file "f18tr.dat". The default on the first execution of START is .T. Reset to .F. after "f18tr.dat" is read in.

(.F.) no action

LLIMDF logical switch

(.T.) Assign hardwired values to array of upper and lower bounds on elements of XTRIM variables. Trim algorithm confines search to this space. The hardwired values are defined in array DEFLIM in subroutine TRIM.

(.F.) Use limit values read from "f18tr.dat" file. (default)

LLNCSY logical switch, used to control the 'LN' exogenous inputs that can be created to support the 'ANALYZ' command in ACSL. Dictates whether the exogenous inputs available to the ANALYZ option, which are used to calculate _LNI inputs, are symmetric/antisymmetric quantities or right/left quantities.

(.T.) _LNI = _SYLN + _ASLN (default)

(.F.) _LNI = _LN

where _LNI is summed with actual control surface position in degrees. Examples of _LNI variables and DSRLNI (left stabilator), DSLLNI (right stabilator), and DRLLNI (left rudder).

LPCAP logical switch

(.T.) Put dynamic check perturbation on lateral stick input.

(.F.) no action (default)

LPCRP logical switch

(.T.) Put dynamic check perturbation on rudder pedal input.

(.F.) no action (default)

LPCSP logical switch

(.T.) A dynamic check perturbation is added to the longitudinal stick.

(.F.) no action (default)

LQSE logical switch - passed to subroutine SFAERRF and USAERRF - used to enable/disable the quasi-static-elastic (QSE) modeling option in the aerodynamic model
normal QSE aerodynamics. All flex/rigid ratios and increments apply.
(default)

(F.) All flex/rigid ratios and increments are set to limiting value as altitude becomes large or density goes to zero.

LRDFTI logical switch - used to drive control surface positions according to a data file - as would occur with flight test data

(T) Subroutine FTDRDF is called. Data is read from file="mhftdi.dat".
(F) no action (default)

LRDWR internal integer switch - intermediate flow control switch set in the simulation and used to control action in call to subroutine RDWRTR - can not be set by runtime commands

(1) causes f18tr.dat trim file to be read in (default)
(2) causes f18tr.dat trim file to be written on

LRTE logical switch - passed to subroutine SFAERRF - used when conducting comparisons to recover the form of the aerodynamic model found in the original DMS simulation

(T) activates form of subroutine SFAERRF that agrees with dmsf18 math model (default)
(F) activates changes discussed in section 5.1 - aerodynamic model

LTHCGL left engine thrust moment about body frame x-axis at c.g., ft-lbs
LTHCGR right engine thrust moment about body frame x-axis at c.g., ft-lbs
LTHDMS logical switch - used to duplicate the DMS throttle position

(T) use DMS scaled throttle position
(F) normal MDC F18 throttle position (default)

LTHVEC logical switch - used to invoke preliminary thrust-vector engine model

(T) preliminary thrust-vector engine model (default)
(F) non-thrust-vector engine model

LTR logical switch

(T) Trim search is initiated after runtime START command. If trim fails, TSTP set = 0. (default)
(F) No trim attempted. Integration proceeds with current i.c.'s until T=TSTP.

LTRFLG internal logical switch - used to indicate current TRIM status

(T) simulation in trim search loop
(F) not in trim search loop

LVDEF logical flag - used to obtain extended output with variable definitions form dictionary

(T) All simulation variable values printed out onto unit=PRN with dictionary definitions taken from unit=29.
(F) no action (default)

LWRFTO logical switch - used for FLT data comparison

(T) subroutine FTDWRF called - data written to file="ftifo.dat"
(F) no action (default)

LWRTR logical switch - used to write new file "f18tr.dat"

(T) Write the next calculated trim values to file "f18tr.dat". Set LWRTR to .F.
(F) no action (default)

MACH Mach number, n.d.
MACHRF Free-stream Mach number at a.r.c., n.d.
MACHTR Mach number to be achieved in trim search if "1" is in the active IXSEL list, n.d.
MARR aerodynamic component of rigid-rigid quadrant of mass matrix
MASS aircraft mass, slugs
MINT minimum integration step size (default value supplied by ACSL)
MIRR inertial component of rigid-rigid quadrant of a mass matrix
MMRR total rigid-rigid quadrant of a mass matrix
MNSPIN FCS logical spin switch. Default = .F. (DO NOT CHANGE).
left engine thrust moment about body frame y-axis at c.g., ft-lbs.
right engine thrust moment about body frame y-axis at c.g., ft-lbs.
bank angle in degrees sought in trim search if "29" included in active IXSEL list.
Will produce coordinated turn if TCASE = 2.
In the fl8bas trim strategy (section 2.2), MUTRMX is equivalent to variable "MUMAX" in ACSL TRIM algorithm (see section 5.2.1, ACSL REFERENCE MANUAL REV. 4.1) - default = 10
maximum number of iterations for simulation trimming scheme - default = 80
maximum integration step size - default = 0.00625 seconds
square root of sum of squares of quaternion intermediate states, used to normalize quaternions at each time step to prevent numerical problems - n.d
minimum number of integration steps in a communication interval. Default = 1. This allows integration step size to be controlled by MXSTP as per recommendation in ACSL manual.
left engine thrust yaw moment about body z-axis at c.g. (TV), ft-lbs
right engine thrust yaw moment about body z-axis at c.g. (TV), ft-lbs
integer switch - FCS flag for thrust vector pitch control blend (1=ON). Default = 1.
number of independent variables for simulation trim search (< NXTRMX)
maximum number of independent variables for simulation trim search (10)
3 element array describing location of ny accelerometer in FS/BL/WL coordinates, inches
lateral acceleration sensor signal, g's
number of dependent variables for simulation trim algorithm (=NXTR)
normal acceleration sensor signal, g's
normal acceleration 1-g steady state removed. NZZR = AZ - 1. g's
FCS logical to override angle-of-attack limiter. Default = .F. (DO NOT CHANGE).
body axis roll rate, rad/sec
gain in left core engine dynamics. 2nd order filter.
gain in right core engine dynamics. 2nd order filter
gain in left core engine dynamics. 2nd order filter
gain in right core engine dynamics. 2nd order filter
Integer that defines page size as number of lines. (45 for NOS, 55 for VAX)
pilot lateral stick position, inches
pilot lateral stick position from flight test data, inches
pilot lateral stick position signal array for IDYNCK = 3
pilot lateral stick position required for trim, inches.
pilot rudder pedal force, lbs
pilot rudder pedal force from flight test data, lbs
pilot rudder pedal force signal array for IDYNCK=3
pilot rudder pedal force required for trim, lbs
pilot longitudinal stick position, inches
pilot longitudinal stick position flight test data, inches
pilot longitudinal stick position signal array for IDYNCK=3
pilot longitudinal stick position required for trim, inches
body axis roll acceleration, rad/sec²
body axis roll rate, degrees/second
gain on dynamic check perturbation command
Euler roll angle, radians
Euler roll angle intermediate state, integral of PHID
Euler roll angle rate of change, rad/sec
Euler roll angle, degrees

WA at a.r.c., ft/sec
body axis inertial acceleration in z-direction, ft/sec^2
(d/dt) of WA, ft/sec^2
d/dt of aerodynamic disturbance component in z-body axis, ft/sec^2
left engine fuel flow
right engine fuel flow
body axis inertial velocity in z-direction i.c., ft/sec
time span to hold step input dynamic check perturbation command,, default = 1.0 seconds
water line coordinate of the center of gravity, inches
water line coordinate of the engine/airframe interface, right/left engine, 100.0 in.
water line coordinate of the aerodynamic reference center, = 100.0 inches
aircraft weight, lbs
z-body component of aerodynamic disturbance velocity, ft/sec
air data probe alpha with source noise added, degrees
x-direction distance from c.g. to a.r.c., ft
A.21

**XBAR** normalized x-location of accelerometer from c.g., n.d.

**XD** aircraft inertial ground track velocity in track direction, ft/sec

**XDDWG** \( \frac{d}{dt} \) of XDWG, ft/sec²

**XDWG** aerodynamic disturbance velocity component in x-earth frame direction, ft/sec

**XDWGIC** aerodynamic disturbance velocity component in x-earth frame direction - initial condition, ft/sec

**XHM1** sensed static pressure breakpoint vector

**XRFCG** 'x' component of the location of right (left) engine/airframe interface point in c.g.-centered body frame, \( = \frac{-(FSENG - FSCG)}{I^2} \), ft.

**XTHCG** total thrust force at c.g. in body x-direction (TV), lbs

**XTHCGL** left engine thrust force at c.g. in body x-direction (TV), lbs

**XTHCGR** right engine thrust force at c.g. in body x-direction (TV), lbs

**XTRLM** 2 by 30 array with upper and lower limits on XTRIM independent variables

**XTVL** left engine thrust force in body x-direction (TV), lbs

**XTVR** right engine thrust force in body x-direction (TV), lbs

**YARF** y-direction distance from c.g. to a.r.c., ft

**YBAR** normalized y-location of accelerometer from c.g., n.d.

**YD** aircraft inertial ground track velocity in cross-track direction, ft/sec

**YDDWG** \( \frac{d}{dt} \) of YDWG, ft/sec²

**YDWG** aerodynamic disturbance velocity component along earth frame y-axis, ft/sec

**YDWGIC** aerodynamic disturbance velocity component along earth frame y-axis - initial condition, ft/sec

**YGKAO2** sensed angle-of-attack gain table

**YGKAOA** sensed angle-of-attack gain table

**YRFCGL** 'y' component of the location of left engine/airframe interface point in c.g.-centered body frame, \( = \frac{(BLENGL - BLCG)}{12} \), ft.

**YRFCGR** 'y' component of the location of right engine/airframe interface point in c.g.-centered body frame, \( = \frac{(BLENGR - BLCG)}{12} \), ft.

**YSAS** FCS logical for yaw SAS on. Default = .T. (DO NOT CHANGE)

**YTHCGL** left engine thrust force at c.g. in body y-direction (TV), lbs

**YTHCGR** right engine thrust force at c.g. in body y-direction (TV), lbs

**YTVL** left engine thrust force at nozzle in y-body direction (TV), lbs

**YTVR** right engine thrust force at nozzle in y-body direction (TV), lbs

**ZARF** z-direction distance from c.g. to a.r.c., ft

**ZBAR** normalized z-location of accelerometer from c.g., n.d.

**ZDDWG** \( \frac{d}{dt} \) of ZDWG, ft/sec²

**ZDWG** aerodynamic disturbance velocity component along earth frame z-axis, ft/sec

**ZDWGIC** aerodynamic disturbance velocity component along earth frame z-axis - initial condition, ft/sec

**ZRFCG** 'z' component of the location of right (left) engine/airframe interface point in c.g.-centered body frame, \( = \frac{-(WLENG - WLCG)}{12} \), ft.

**ZTHCGL** left engine thrust force at c.g. in body z-direction (TV), lbs

**ZTHCGR** right engine thrust force at c.g. in body z-direction (TV), lbs

**ZTVL** left engine thrust force in body z-direction (TV), lbs

**ZTVR** right engine thrust force in body z-direction (TV), lbs

**ZZABL** \( \frac{d}{dt} \) of left engine thrust in AB before rate limiting, lbs/sec

**ZZABR** \( \frac{d}{dt} \) of right engine thrust in AB before rate limiting, lbs/sec
APPENDIX B - EXAMPLE CASES

Trim to Level Flight (TCASE=1)

The following wings level (TCASE=1) trim cases are demonstrated by an example terminal session:

1. M=0.6, H=10,000 (ft), flight path angle (γ) = 0.
2. M=0.8, H=10,000 (ft), flight path angle (γ) = 0.
3. α = 5°, H=10,000 (ft), flight path angle (γ) = 0.
4. α = 10°, H=10,000 (ft), flight path angle (γ) = 0.

Commands entered at the keyboard are in **bold courier**. The program and VMS responses are in **plain Courier**. Comments inserted after the session to explain actions are in *italics*.

Steady State Pull-Up (TCASE=3)

The following steady-state pull-up (TCASE=3) trim cases are demonstrated by an example terminal session. The session is begun by reading in the TCASE=1 trim data file f18tr.dat, then using run time commands to set up the pull-up trim.

1. $M=0.6$, $H=10,000$ (ft), wings level, $TCASE=1$, flight path angle ($\gamma$) = 0.
2. $M=0.6$, $H=10,000$ (ft), $TCASE=3$, $GLOAD (n_2) = 2$ g's.
3. $M=0.6$, $H=10,000$ (ft), $TCASE=3$, $GLOAD (n_2) = 4$ g's.

AGCB9$ copy f18tr_tcl.dat f18tr.dat  
Copy f18tr.dat file used for $TCASE=1$ trim cases into generic file read by f18bas simulation.

AGCB9$ acsl/run f18bas

The mathematical model and associated computer program to simulate a twin-tailed high performance fighter airplane (McDonnel Douglas F/A-18) are described. The simulation program is written in the Advanced Continuous Simulation Language language. The simulation math model includes the non-linear, six degree-of-freedom rigid-body equations, an engine model, sensors, and first order actuators with rate and position limiting. A simplified form of the F/A-18 digital control laws (version 8.3.3) are implemented. The simulated control law includes only inner loop augmentation in the up and away flight mode. The aerodynamic forces and moments are calculated from a wind-tunnel-derived database using table look-ups with linear interpolation. The aerodynamic database has an angle-of-attack range of -10° to +90° and a sideslip range of -20° to +20°. The effects of elastic deformation are incorporated in a quasi-static-elastic manner. Elastic degrees of freedom are not actively simulated. In the engine model, the throttle-commanded steady-state thrust level and the dynamic response characteristics of the engine are based on airflow rate as determined from a table look-up. Afterburner dynamics are switched in at a threshold based on the engine airflow and commanded thrust.
