The observation that rms slopes obtained from direct inversion of the altimetry data are consistent, at least in a general way, with values derived from template fits [1] provides some confidence that both these procedures are reliable. Since the recovered functions from inversion $\delta \phi (\theta)$ do not depend on $a$ priori specification of an analytic function, we expect to find differences between our results and those obtained via the template method as our analysis proceeds.

Our result that an exponential scattering function can provide better agreement with data than the widely used Hagfors function is significant in terms of its implications for the surface. Although the difference is not large, it is convincing. A gaussian surface model is derived by assuming that the surface is gently rolling. A Hagfors surface must have at least a few flat segments and some "edges" in order to justify use of an exponential autocorrelation function. The degree to which a fresh planetary surface has been turned over and smoothed may be expressed in the degree to which its scattering is described by gaussian functions rather than Hagfors functions. The exponential function requires that there be more or larger flat-lying segments than even the Hagfors function requires. We note that while the exponential law works best for Venus, just the opposite is the case for the Moon [2]. It seems likely this difference reflects underlying differences in processes of erosion and deposition and of materials on the two bodies.

Our results from SAR image analysis to date are limited. We have found a smooth region (in altimetry data) east of Alpha Regio where SAR backscatter cross section is lower than predicted by the Muhlemann function, suggesting that the same scattering mechanisms apply at both nadir and $\phi = 30^\circ$ and $35^\circ$. East of Maxwell, SAR backscatter is above average, but our estimates of rms slopes and those derived from template fitting [3] indicate that this is an "average" region in its nadir backscatter. The difference could be accounted for by the presence of small-scale roughness that is not apparent to the altimeter but scatters relatively strongly at oblique angles.

The Doppler offset observations appear to be real and a manifestation of a geophysical or geological state of the surface. They show global patterns that include a great circle at equatorial latitudes (roughly following the band of equatorial highlands that includes Aphrodite Terra, Eistila Regio, and Beta Regio) and at least part of another (constant latitude) circle at $40^\circ$-$50^\circ$ N. Large-scale surface slopes from Pioneer Venus topography [4] correlate to some extent, but are inadequate by themselves to cause the displacements observed. Small-scale "shingles" or other asymmetric scattering surfaces (for example, sand dunes [R. A. Arvidson, personal communication]) could contribute, but acquiring independent confirming data will be difficult. Local slopes of $0.3^\circ$ on kilometer scales may also be important [P.G. Ford, personal communication], but more needs to be learned of their distribution. A concentration of negative offsets between Sapas Mons and Rusalka Planitia, where the large-scale surface gradient is perpendicular to the Magellan track, indicates that this phenomenon need not be associated with large-scale slopes. Global-scale "zones of disruption" [5] may have led to surface modification, which is expressed in small-scale surface features but does not necessarily show up in the large-scale topography.

radar backscatter cross sections and low emissivities. They suggest that these craters are relatively young and that these radar-bright floors are the result of wavelength scale roughness and high Fresnel reflectivity material. With time, modification processes remove the parabolic deposits and alter the crater floors to lower backscatter cross sections, lower Fresnel reflectivities, and higher emissivities that match those typical of the older craters without parabolic features.

We have plotted the specific backscatter cross sections for the 144 craters used in our analysis (Fig. 2). The dashed line is the Muhleman Law, which is the derived average scattering function based on Pioneer Venus SAR observations and used by the Magellan project to normalize the backscatter cross sections. Because all but one (Mead) of the low-emissivity crater floors have stronger backscatter than most craters, this supports an association between low-emissivity and high-backscatter cross sections for most craters on Venus. Of these 16 low-emissivity craters, 7 are peak ring, 6 are central peak, and 3 have no floor structure. Ten of these craters have associated parabolic features.

Interpretations: To help us interpret the materials in the crater floors, we have used a relation between bulk density and relative dielectric constant for lunar samples of rocks and “soils” [5]. A Fresnel reflectivity near 0.38 can be inferred [3] from the emissivity (0.62) of crater floor materials of Boleyn (Table 1) to yield a calculated dielectric constant of 17.8 [6]. The inferred bulk density, which is 4380 kg/m³ (range: 3880–5090), is much too large for common basaltic rocks. More probable bulk densities of basaltic rocks, which have dielectric constants near 8 to 9 [7], lie in the range of 2600–3000 kg/m³.

Low emissivity values for the venusian highlands can best be explained by the presence of conducting minerals, such as iron pyrite, iron sulfides, or iron oxides [8]. We also suggest that inclusions of conducting minerals or particles in the crater floor materials could account for the low emissivities and high Fresnel reflectivities. Materials containing these particles may have been (1) excavated from depth in the crust during the impact process, (2) derived from the projectile that produced the crater, (3) formed by physical-chemical reactions associated with the impact process (including impact melts), (4) extruded into the crater by volcanic processes, and (5) produced by some combination of these processes. The absence of low-emissivity signatures on the crater flanks and bright outflows suggest that 1, 2, and 3 are unlikely because the low emissivities are confined to crater floors. It may be possible, however, that atmospheric shocks associated with the impacts confine materials or impact metamorphism is confined to the materials of the floors.

Some of the craters are clearly filled with postcrater lavas while others may be filled with impact melts. In the case of the crater Bonheur, the flooded interior basin has a lower emissivity and a smaller backscatter cross section than the outer basin. This observation supports an endogenic lava flow with low emissivity (possibly high in iron content) that has flooded the interior basin. Two low-emissivity craters reside on the tessera and one of these appears to be partly flooded by lava. This means that low emissivity lavas may erupt from magma sources beneath the tessera as well as the plains. Backscatter cross sections for both the floors and outflows of some craters, such as Stowe, are about the same and this suggests the materials of the floors include impact melts. The next step is to investigate how this low-emissivity material could, weather to the

higher emissivity values (0.8–0.9) on the plains and on the other crater floors and to investigate whether young lava flows also exhibit low emissivities. FLOOR-FRACTURED CRATER MODELS FOR IGNEOUS CRATER MODIFICATION ON VENUS. R. W. Wichman and P. H. Schulz, Department of Geological Sciences, Brown University, Providence RI 02912, USA.

Introduction: Although crater modification on the Earth, Moon, and Mars results from surface erosion and crater infilling, a significant number of craters on the Moon also exhibit distinctive patterns of crater-centered fracturing and volcanism that can be modeled as the result of igneous crater modification [1–5]. Here, we consider the possible effects of Venus surface conditions on this model, describe two examples of such crater modification, and then briefly discuss the constraints these craters may place on conditions at depth.

Floor-fractured Crater Model: On the Moon, most floor-fractured craters occur near the lunar maria [1,6,7] or along basin ring faults [5], and commonly contain ponded mare units and dark mantling deposits [1,8,9]. Fracturing is confined to the crater interior, and, in the more modified craters, uplift of the crater floor as a single coherent unit results in a distinctive moat-like feature zone in the crater wall region [1,4]. In some cases, later volcanism floods this moat structure or buries the entire floor [1,3].

Although viscous relaxation can produce uplift of the crater floor [10–12], shallow, laccolithic intrusion beneath the crater floor provides a model consistent with observations on the Moon. As discussed elsewhere [1,4,5], intrusions apparently begin in a neutral buoyancy zone near the base of the crater-centered breccia lens through the lateral growth of a sill-like magma body. Both the increased lithostatic pressures and diminished impact brecciation beneath the crater walls, however, enhance resistance to such lateral intrusion growth beyond the crater floor region, thereby evolving into vertical, laccolithic intrusion growth described by [13]. During vertical growth, the crater floor rises through a piston-like uplift, while ring faulting near the edge of the intrusion produces the moat structures outside this uplift.

For a laccolithic intrusion, crater modification is controlled by parameters that allow assessing conditions at depth [4,5]. Since elastic deformation should not thin the uplifted crater floor section, the amount of uplift essentially reflects the intrusion thickness. If the uplifted floor diameter delineates the laccolith size at depth, then the model [13] can be used to estimate both the magma pressure driving deformation and an effective thickness for the crater floor materials overlying the intrusion. The derived magma pressures then help constrain the length of the magma column beneath the intrusion, whereas the inferred floor thickness provides a model for both the intrusion depth and breccia thickness in a given crater [4,5].

Floor-fractured Craters on Venus: The evidence for widespread volcanism on Venus [14] would seem to favor igneous crater modification. Four significant differences between conditions on Venus and on the Moon may modify the processes of crater-centered igneous intrusion. First, where the anorthositic crust on the Moon is apparently equivalent in density or less dense than most mare magmas [15], the basaltic crust on Venus should be denser than basaltic melts and may be thinner than the lunar crust as well. Consequently, basaltic magmas on Venus are more likely to rise to the surface than magmas on the Moon, perhaps decreasing the likelihood of crater-centered intrusions at depth [4]. Second, the lunar crust has been extensively fractured by successive, overlapping impact events. The resulting combination of a megaregolith and basin ring faults, therefore, provides a number of conduits through which magma can enter individual crater-centered breccias. In contrast, the crust on Venus appears to be more coherent; hence, magma may not favor breccias beneath craters on Venus. Instead, a crater-centered intrusion may first require deformation by a regional fracture system. Third, the higher surface gravity on Venus should reduce the fracturing porosity of an impact breccia, thereby reducing the density contrast required for a shallow zone of crater-centered neutral buoyancy. High surface gravity also should consolidate impact breccias at depth, which may produce thinner breccia lenses on Venus than on the Moon. As a result, the uplifted floor plate on Venus should be thinner than on the Moon, and floor fracturing would then be expected to be more polygonal, i.e., reflecting inhomogeneities in the floor rather than acting as a coherent block. Fourth, since the increased surface temperatures on Venus may allow annealing of impact breccias over time, both the fracture density beneath a Venus crater and the probability of an igneous intrusion also may decrease as a function of crater age.

Most impact craters on Venus do not exhibit floor fractures comparable to examples on the Moon. Instead, either volcanic infilling occurs or craters are simply engulfed rather than participate in surface volcanism. Figures 1 and 2, however, illustrate two craters that closely resemble floor-fractured craters on the Moon. For reference, both craters occur in ridged lowland plains with elevations of approximately ~500 m to 500 m, relative to the mean planetary radius. The first of these craters (Fig. 1) is 48 km in diameter and exhibits a scarp-bounded central floor plate 32 km in diameter in which an additional pattern of concentric failure can be
