ABSTRACT

We present results for two real-time filters prototyped for the Compton Gamma Ray Observatory (GRO), the Extreme Ultraviolet Explorer (EUVE), the Cosmic Background Explorer (COBE), and the next generation of Geostationary Operational Environmental Satellites (GOES). Both real and simulated data were used to solve for attitude and gyro biases. These filters promise advantages over single-frame and batch methods for missions like GOES, where startup and transfer-orbit operations require quick knowledge of attitude and gyro biases.

1. INTRODUCTION

Mishaps of the distant past have prevented sequential filters from becoming part of the operational ground support systems in the Flight Dynamics Facility (FDF). Experience gained over the past few years with prototype filters for several spacecraft, however, bolsters the conviction that sequential filters have a place in real-time attitude and gyro bias estimation in the FDF.

Two very different filters, filter QUEST and the Real-Time Sequential Filter (RTSF), both show themselves to be reliable alternatives to the original single-frame QUEST for real-time systems. As long as attitude is continuously observable, divergence does not appear to be a problem, and the filters work over a wide range of tuning parameter values.

This article provides an account of recent attitude and gyro bias filtering experience using data from COBE, GOES, GRO, and EUVE. The filters perform well and provide attitude and gyro bias solutions in less time than would be necessary to obtain a batch estimate.

2. FILTER QUEST

Filter QUEST is a sequential version of the q-algorithm as implemented in the widely used QUEST software (Reference 1). The q-algorithm only estimates attitude, but for the sake of accuracy, it is almost essential that gyro biases be estimated as well. In order to make filter QUEST satisfy the demand for gyro biases, a bias filter was added to run in parallel with the attitude filter.

The bias filter takes the attitude predicted using gyro measurements \( \bar{q}(\cdot) \) and compares it to the attitude updated using sensor measurements \( q(\cdot) \). First, the difference between the two attitude quaternions is computed:

\[
\Delta q = \begin{bmatrix} \Delta q_1 \\ \Delta q_2 \\ \Delta q_3 \\ \Delta q_4 \end{bmatrix} = \begin{bmatrix} q(-) - q^{(-)} \\ -q(-) + q^{(-)} \\ q(-) - q^{(-)} \\ -q(-) + q^{(-)} \end{bmatrix} = \begin{bmatrix} \Delta q_1 \\ \Delta q_2 \\ \Delta q_3 \\ \Delta q_4 \end{bmatrix} \tag{1}
\]

Then, this difference is transformed into a rotation vector \( \Delta \vec{a} \) and divided by the time step \( \Delta t \) to provide an observation of the gyro bias \( \Delta \vec{b} \):

\[
\Delta \vec{a} = \frac{2 \text{atan} 2 \left( \frac{\Delta q_1^2 + \Delta q_2^2 + \Delta q_3^2}{\Delta q_1^2 + \Delta q_2^2 + \Delta q_3^2} \right)} {\sqrt{\Delta q_1^2 + \Delta q_2^2 + \Delta q_3^2}} \begin{bmatrix} \Delta q_1 \\ \Delta q_2 \\ \Delta q_3 \\ \Delta q_4 \end{bmatrix} \tag{2}
\]

These observations are averaged using the same fading memory parameter, \( \alpha \), as is used for the attitude (Reference 2). The fading memory parameter is a scalar between 0 and 1.

\[
\bar{b}_n = \bar{b}_{n-1} + (1 - \alpha) \frac{\Delta \vec{a}_n}{\Delta t} \tag{3}
\]
The enhanced filter QUEST was originally applied to COBE where the spin (X-axis) gyro bias is of primary concern. The COBE Fine Attitude Determination System (FADS) found the X-axis gyro bias to be 14.4 degrees per hour (deg/hr) for these data. Figure 1 through Figure 3 show the filter QUEST bias solutions for different values of $\alpha$. An initial bias value of 0 deg/hr was used. Figure 1 shows that $\alpha$ equal to 0.9 is too low to filter out sensor noise. In Figure 2, the bias converges to within 1 deg/hr of the FADS bias in only 6 minutes. Setting $\alpha$ to 0.999 as in Figure 3 further reduces the noise but slows convergence.

Figure 4 differs from the preceding figures in that the initial bias is close to the correct value. Filter QUEST with $\alpha$ equal to 0.999 shows variation in the estimated bias. The COBE X-axis gyro is known to be temperature sensitive, and the enhanced filter QUEST may be useful in studying this sensitivity.

The COBE solutions were obtained by replacing the standard QUEST subroutines in the Coarse Attitude Determination Subsystem (CADS) with the new filter QUEST subroutines. All the data were synchronized in the Data Adjuster Subsystem (DA), and every data point was processed. The filter is updated every half-second.

Filter QUEST has also been tested with simulated data for GOES. In this case, the standard QUEST routines were replaced with their filter counterparts in the Real-Time Attitude Determination System (RTADS). There, at most one data point can be processed for every 8 seconds (sec) of data, and the different data types may come from any time in that interval. These attributes of RTADS are clearly undesirable, but there has not yet been time to change them.

Nonetheless, Figure 5 shows the filter QUEST roll and pitch bias solutions converging over the course of 15 minutes (yaw is similar). The data were simulated to reproduce that expected during the GOES transfer orbit but without systematic errors other than gyro biases. The filter was started from initial estimates of 0 deg/hr and was given an $\alpha$ value of 0.9999, which should slow the convergence. There are initial transients and oscillations in the bias solutions, but even with the less than ideal RTADS preprocessing and a fairly short data span, biases approach the batch estimated values. The filter solutions are within 10% for yaw, 30% for pitch, and 40% for roll.

### 3. RTSF

The RTSF is a scaled-down version of the extended Kalman filter originally prototyped for the Earth Radiation Budget Satellite (ERBS) (References 3 and 4). Whereas the 37-component state vector of the ERBS filter included various sensor misalignments and scale factors, the RTSF estimates a 7-component state vector consisting of the attitude quaternion and the three components of the gyro bias (Reference 5). The objective of the present study is to evaluate the RTSF in a real-time situation with its attendant data processing problems. To this end, we integrated the RTSF into current real-time attitude determination software and evaluated it using real telemetry data from GRO and simulated data from EUVE.

The theory of the filter has been presented elsewhere (References 3 and 4) and will not be repeated here, except to note that the GRO RTSF updates the attitude quaternion using a multiplicative method. Thus, if $(\phi, \Omega, \mu)$ are three small Euler angles representing corrections to the attitude estimate, the corresponding correction to the quaternion is specified by

\[
\delta \mathbf{q} = \begin{bmatrix}
\phi/2 \\
\Omega/2 \\
\mu/2 \\
1
\end{bmatrix}
\]

and the quaternion is updated through:

\[
\bar{q}_{k+1}(+) = \bar{q}_{k+1}(-)\bar{q}_{k}^{-1}
\]
Figure 6. Estimates of the roll (Euler) angle. Solid line represents the OBC estimate, and ‘x’ represents the RTSF estimates. The a priori roll estimate was +120 deg.

Figure 7. Estimates of the yaw (Euler) angle. Notation is that of Figure 6. The a priori yaw estimate was −20 deg.
Figure 8. RTSF estimates ('x') of the gyro bias along the yaw axis. The horizontal line represents the bias of +2.4 deg/hr included in the gyro data input to the RTSF. The a priori bias estimate was 0.0 deg/hr.
EUVE: RTSF (with FHST)
Roll rate = 1.3 rpo
FSS biased
TAM misaligned & noisy
Discontinuities occur at new star identifications

Figure 9. EUVE yaw angle determined by RTSF and single-frame QUEST. The dashed line marked “OBC” is the true yaw angle.

EUVE: RTSF (with FHST) Roll Gyro Bias
Roll rate = 1.3 rpo

EUVE: RTSF (with FHST)
Inertial case
Attitude noise less than 15 arcsec (1-σ) on all axes

Figure 11. EUVE RTSF solution for pitch angle. True pitch is constant at 9.82 deg. FSS misalignment causes the 0.1-deg offset.

EUVE: RTSF (with FHST) Gyro Biases
Inertial case
Bias errors less than 0.2 deg/hr (1-σ) on all axes

Figure 12. EUVE RTSF solution for the gyro biases. The true biases are all zero in this example.
filters out random noise, not systematic errors. The discontinuities in attitude are under 0.04 deg. They can be greatly reduced by tuning the filter for a longer memory and increasing the sensor noise parameters to put less reliance on current incoming data. However, this leads to noisier solutions and longer bias convergence times.

Figure 11 and 12 show a case where EUVE is inertially pointing with the Sun in view of the FSS and an identified star in FHST-1. The attitude solution converges within 1 minute (the filter is updating once per second), with residual noise under 15 arcsec (1-σ). After 4 minutes, the gyro bias errors are under 0.2 deg/hr (1-σ) and still decreasing.

4. CONCLUSIONS

Adding a simple gyro bias estimator to filter QUEST gave COBE and GOES biases within 1 to 2 deg/hr of the batch estimator values. This filter proved stable under a wide range of memory length parameter values. Increasing the memory parameter slowed response and smoothed the time history but did not affect the final result. The COBE data used were all clean and synchronized. The GOES data were simulated and clean but not synchronized. Attitude was continuously observable for both spacecraft.

For the GRO RTSF, using real data provided a useful test of the filter’s performance in a real-time situation. The attitude errors using FSS and TAM data depended upon Sun observability by the FSS and ranged from 0.5 to 2 deg; the gyro bias errors varied correspondingly between 0.5 and 20 deg/hr.

The GRO RTSF proved to be robust in the presence of gyro data anomalies. However, its solutions for roll angle and roll gyro bias are relatively noisy and slow to converge due to the limitation to only FSS and magnetometer measurements (the Sun being close to the roll axis). The inclusion of FHST data in the EUVE RTSF greatly improves the solutions. The EUVE RTSF solutions were subject to offsets and small discontinuities due to misalignments and biases. This problem is expected to affect the early stages of any mission until the full ground support system estimates these systematic errors.
