September 1942
Fatigue tests were conducted on six specimens made from 3/4-inch-diameter 17S-T rolled-and-drawn rod for the purpose of obtaining additional data on the fatigue life of the material at stresses up to the static strength. The specimens were tested in direct tension using a stress range from zero to a maximum in tension. A static testing machine was used to apply repeated loads in the case of the first three specimens; the other three specimens were tested in a direct tension-compression fatigue machine.

The direct-stress fatigue curve obtained for the material indicates that, in the range of stresses above about two-thirds the tensile strength, the fatigue strength is higher than might be expected by simply extrapolating the ordinary curve of stress plotted against number of cycles determined at lower stresses.

INTRODUCTION

Fatigue-test results are ordinarily plotted with stress as ordinates and number of cycles as abscissas. The fatigue-strength curves for aluminum alloys usually cover a range of cycles starting at some value around 50,000 and extending to about 500,000,000. The larger of these two numbers is an arbitrary limit used to define endurance limit; and the smaller is a value representing limitations imposed by capacity of testing equipment, excessive yielding of material in specimens, and various other practical considerations. For some applications of aluminum alloys, useful engineering information would be provided by extending the curves backward to smaller numbers of cycles and higher stresses. Such an extension of a curve is difficult, however, because some of the stresses involved exceed the yield strength of the material with
the result that there is considerable yielding of the specimen, and it is therefore difficult to maintain the loading conditions constant during testing. In the case of bending-fatigue tests there is the additional difficulty of accurately determining the extreme fiber stress after yielding begins.

In order to avoid some of these difficulties it was decided to limit this investigation to direct-stress fatigue tests for cycles of stress ranging from zero to a maximum in tension (stress ratio: minimum/maximum = 0). It was further decided to test each of the most highly stressed specimens in an ordinary Amseler static testing machine using a series of repeated loadings; each loading was applied by the operator in the manner that he would apply an ordinary static loading. This scheme of testing would not be practical, of course, for a large number of tests, but it offered an opportunity to complete the fatigue curve without the necessity of developing any specialized testing equipment for the range of low numbers of cycles. The material selected was 17S-T rolled-and-drawn rod for which a direct-stress fatigue curve for zero stress ratio was already available starting at about 100,000 cycles.

The object of this investigation was to obtain additional direct-stress fatigue-strength data for 17S-T so that the fatigue-strength curve could be plotted for the full range of numbers of cycles from static loading to the endurance limit:

MATERIAL

The material used for this investigation was 3/4-inch-diameter 17S-T rolled-and-drawn rod marked P-301. The direct-stress fatigue curve for a stress ratio of zero, as determined on the direct tension-compression testing machines (reference 1, fig. 5) was already available at the beginning of this investigation and is shown in figure 1. It will be noted that this curve covers the range of cycles from about 100,000 to about 500,000,000, a range commonly covered in conventional fatigue testing of aluminum alloys. The chart on which this curve is plotted does not provide room to extend the curve back as far as desired into the low numbers of cycles. For this reason a more condensed chart is shown in figure 2 in which the
full range of cycles from 1/2 (static loading) up to 500,000,000 (endurance limit) can be plotted. This chart shows clearly that a considerable portion of the fatigue curve was undefined by the existing data. This undefined portion of the curve was, of course, the subject of this investigation.

The tensile strength of the material represents the end point of the fatigue curve and therefore assumes considerable importance in this investigation. The value used in this investigation (60,970 lb/sq in.) was determined by conducting a static ultimate-load tensile test on one of the regular specimens that had been prepared for the fatigue tests. The Amsler autographic diagram taken on this specimen showed a first departure from the straight line at 38,400 pounds per square inch, which is an approximate indication of the yield strength.

PROCEDURE

Tests in this investigation were made on specimens of the type illustrated in figure 3, which is the type of specimen ordinarily used in the direct tension-compression fatigue testing machine. After they had been machined, all specimens were carefully polished with strokes parallel to the axis of the specimen. Care was taken in all tests to avoid any scratching or marking of the surfaces of the reduced portion of the specimen.

Two of the tests, in addition to the one for the tensile-strength determination, were made in a 20,000-pound-capacity Amsler testing machine with a load range of 2000 pounds. These specimens had a nominal minimum diameter of 0.200 inch. They were tested by repeatedly applying and releasing a load equal to a predetermined percentage of the tensile strength of the material. The first specimen was tested at 98 percent of the tensile strength and failed after 76 applications of the load. The second specimen was loaded to 92 percent of the tensile strength and showed no evidence of failure after 2000 applications of the load. The time required to test this specimen to failure was considered prohibitive, and the test was discontinued.
Three specimens were tested in the direct tension-compression fatigue-testing machine in the usual manner, except that special attention was given to the elimination of the effects of yielding in the specimens because of the high stresses encountered. It is common practice in testing specimens in the direct tension-compression fatigue machine to check the load after the first few cycles in order to make sure that yielding of the specimen or other factors have not changed the loading. In these tests at high stresses yielding of the specimen was expected to be of considerable importance, and the specimen was deliberately preloaded in the machine for several minutes and the load adjusted afterward to avoid any reduction in the load during the test because of progressive yielding of the specimen.

The first of the three tests in the tension-compression fatigue-testing machine was made on a specimen with a nominal diameter of 0.200 inch, but it was decided on subsequent specimens to reduce the diameter to a nominal diameter of 0.160 inch in order to reduce the load on the testing machine. The reduction of the minimum diameter of the specimen was made without altering any of the other dimensions shown in figure 3.

RESULTS AND DISCUSSION

Table I presents a complete summary of the data obtained in this investigation. These data have been plotted in the form of an S-N curve in figure 4. It will be noted that this curve covers the complete range of cycles from static loading to the endurance limit, as intended, and that the test results obtained on the Amseier testing machine seem to agree very well with the results from the direct tension-compression fatigue-testing machine. It will be further noted that the newly defined portion of the fatigue curve connects reasonably well with the previously determined portion of the curve, although the transition is a rather abrupt change in direction of the curve. Perhaps the most notable feature of the complete curve is that the fatigue strength of the material in the range of stresses above about two-thirds the tensile strength is considerably greater than one might expect by simply extrapolating the ordinary S-N curve determined at lower stresses.
CONCLUSION

The direct-stress fatigue curve shown for the 3/4-inch-diameter 17S-T rolled-and-drawn rod indicates that in the range of stresses above about two-thirds the tensile strength the fatigue strength is higher than might be expected by simply extrapolating the ordinary curve of stress plotted against number of cycles determined at lower stresses.
