REPORT 1189

THEORETICAL AND EXPERIMENTAL ANALYSIS OF LOW-DRAG SUPERSONIC INLETS HAVING A CIRCULAR CROSS SECTION AND A CENTRAL BODY AT MACH NUMBERS OF 3.30, 2.75, AND 2.45

By Antonio Ferri and Louis M. Nucci

SUMMARY

A discussion of inlets having a circular cross section and a central body, designed for high Mach numbers, has been made. The optimum relationship between external and internal supersonic compression has been discussed with respect to the external drag and the maximum pressure recovery. Practical design criteria have been given and tests of inlet configurations designed from these criteria have been presented for Mach numbers of 3.30, 2.75, and 2.45 and for corresponding Reynolds numbers ranging from $3.5 \times 10^6$ to $3.0 \times 10^6$. Values of maximum pressure recovery and shock wave shapes for different combinations of central body and cowling shape and for different positions of central body relative to cowling have been given. The results of the tests have been analyzed and show that, with the proper selection of geometric and aerodynamic parameters, high pressure recovery and low drag can be obtained. Pressure recoveries of 0.57, 0.67, and 0.78 at Mach numbers of 3.30, 2.75, and 2.45, respectively, have been obtained with very low external drag.

INTRODUCTION

In the design of supersonic inlets for ram jets and turbojets, two parameters are of fundamental importance: the maximum pressure recovery obtainable from the inlet for a given Mach number and the drag due to the aerodynamical phenomena of the inlet. The relative importance of the two parameters depends on the practical application being considered; therefore, an exact discussion of the optimum inlet design is not possible. However, in general, it is possible to show that the drag due to the deceleration of flow from high speeds to low speeds becomes more important when the free-stream Mach number increases.

Usually for ram-jet burners and turbojet compressors, the flow must be decelerated to speeds of the order of 0.2 to 0.3 of the speed of sound. Therefore, at low free-stream supersonic Mach numbers of 1.4 to 2.0, the maximum cross-sectional area is at the burner or the compressor. (For the turbojet the actual Mach number in front of the compressor is usually higher than the values of 0.2 and 0.3 previously mentioned, but the total cross section, if the central part of the compressor is also considered, corresponds to Mach numbers of that order.) For this reason, an external shock drag always exists regardless of the type of inlet considered.

Thus, the external shock drag can be efficiently used for the compression of the flow which goes into the inlet. In the range of free-stream Mach numbers between 1.4 and 2.0, it is usually possible to design any particular type of inlet without any large difference in external drag (ref. 1). Therefore, the parameter of external drag is not of primary importance in determining the type of inlet. However, it is important that the aerodynamic design of the inlet be made correctly. This correct design depends essentially on the fact that, in the Mach number range considered, a given external drag must exist and the supersonic deceleration of the flow can produce only a small increase in pressure along the boundary of the stream tube which goes into the inlet. Therefore, the compression and subsequent shock that can be produced in the flow by the entering stream tube cannot be too large. This compression is of the same order as the increase in pressure and corresponding shock necessary at the lip of the cowling to provide an aerodynamically good shape for the body which contains the ram jet or turbojet.

In this lower Mach number range, supersonic inlets with a large part or all supersonic external compression are considered very good because the maximum pressure recovery which can be obtained is higher than for other types of inlets; and with good aerodynamic design, the increase in external drag due to external compression can be reduced or neutralized.

The increase in pressure recovery in this range is useful for two reasons: (1) the thrust per unit mass flow increases; (2) for a constant mass flow the size of the burner decreases because the density in front of the burner is higher. When the size of the burner decreases, the external diameter of the ram jet or turbojet decreases, and thus the overall drag is less.

As the value of the free-stream Mach number increases, the consideration of drag connected with the inlet becomes more important. Indeed, the external shape of the body tends in many cases to approach a cylinder; therefore, the minimum necessary shock drag produced by the external shape of the body which contains the ram jet or turbojet decreases greatly and can approach zero. However, the drag which can be produced by the aerodynamic phenomena due to the external compression of the flow which enters the inlet increases greatly as the Mach number increases.

1 Supersedes recently declassified NACA RML RM 13H13, "Theoretical and Experimental Analysis of Low-Drag Supersonic Inlets Having a Circular Cross Section and a Central Body at Mach Numbers of 3.30, 2.75, and 2.45" by Antonio Ferri and Louis M. Nucci, 1948.
Therefore, the differences in external drag between different types of inlets can be very large. The increase in drag caused by a large external compression is due to the large increase in pressure and to the correspondingly large deviation of the stream direction at the lip of the cowling. The deviation of the stream requires a large inclination of the lip of the cowling with respect to the undisturbed stream; therefore, the ratio of the maximum cross section of the body which contains the inlet to the cross section of the free-stream tube must be large. Now, for a constant velocity in front of the burner or compressor and constant cross section of the burner or of the compressor, the free-stream tube increases when the free-stream Mach number increases; therefore, for Mach numbers greater than those previously considered, the maximum cross section of the ram jet or turbojet occurs at the entrance of the inlet and not at the burner or at the compressor. In this case, an increase of pressure recovery no longer permits a decrease in the size of the body that contains the turbojet or ram jet but in some cases requires an increase of body diameter. In this range of Mach numbers, the drag is a fundamental parameter in the selection of an inlet.

In order to give an idea of the changes which occur when the Mach number increases, a comparison has been made between inlets having all external compression and all internal compression for free-stream Mach numbers equal to 1.6 and 3.0. For a Mach number of 1.6 the pressure recovery which can be expected for an inlet with internal compression is of the order of 0.87 (ref. 2), whereas for an inlet with all external compression the pressure recovery can be of the order of 0.94 (ref. 1). If the cross-sectional areas of the free-stream tubes are assumed as the areas of reference and are considered equal for both cases, then the maximum cross section of the burner for a Mach number in front of the burner of 0.3 is 1.87 times the cross section of the free-stream tube for the case with internal compression and 1.73 times the cross section of the free-stream tube for the case with external compression. An 8-percent decrease in maximum cross section of the burner is obtained for the inlet with external compression. If the frustum of a right circular cone having a 6° half-angle is assumed as the external shape of an inlet with internal compression (fig. 1), the pressure coefficient \( P \) at the lip of the cowling is 0.192 and becomes of the order of 0.053 at some distance from the lip. If the local Mach number at the entrance of the inlet is assumed to be 1.0, the inclination of the lip for the inlet with external compression becomes of the order of 14° and the pressure coefficient \( P \) becomes 0.64. However, along the surface the pressure coefficient decreases very rapidly to zero and the drag of the two inlets is of the same order of magnitude (ref. 1).

If a pressure recovery of 0.49 at a Mach number of 3.0 is assumed for an inlet with all internal compression and the Mach number in front of the burner is fixed at 0.30, the cross-sectional area of the burner is 0.981 of the cross-sectional area of the free-stream tube (fig. 2). Therefore, for such an inlet, the external shape of the ram jet or turbojet can be cylindrical with a diameter equal to that of the free-stream tube, and the shock drag can be zero. If the speed in front of the burner or compressor decreases slightly, the maximum cross section of the ram jet or turbojet increases but still is of the same order of magnitude as the cross section of the free-stream tube. When an inlet with all external compression is considered for the same Mach number, the deviation of the lip of the cowling must be of the order of 33° if the external shock is at the lip of the cowling, and, therefore, the pressure coefficient at the lip will be of the order of \( P = 1.036 \). Therefore even if a very rapid expansion is introduced near the lip, the external drag coefficient will always be very large. Because a deviation of 33° is necessary at the lip, it is apparent that the maximum diameter of the body which contains the inlet (fig. 2) must be larger than the free-stream tube diameter. For high free-stream Mach numbers of the order of 3.0, a compromise must be made between the increase in pressure recovery and the increase in drag. Therefore, it is necessary to determine the pressure recovery for inlets with low external drag in order to have information for the proper selection of inlets.

On the basis of these considerations, a preliminary investigation was conducted in the Gas Dynamics Section of Langley Aeronautical Laboratory in order to determine the optimum pressure recovery which could be obtained for
low-drag inlets in the range of Mach numbers between 2.45 and 3.30. The results permit a comparison of these inlets with inlets designed primarily by the criterion of obtaining very high pressure recovery (refs. 3 and 4) without consideration for reducing the external drag. The inlets investigated were nose inlets with partially external and partially internal supersonic compression. They were designed after a preliminary analysis of the conditions required in order to have low external drag. In these inlets, compression through a conical shock is used to obtain external compression. Different values of cone angle, central-body diameter, cowling shape, and central-body position relative to the cowling were included in the tests. The results provide a good aerodynamic design of the inlet for every practical case, because in practical applications the maximum diameter of the body which contains the ram jet or turbojet is given. When the external diameter of the body and the size of the free-stream tube of the entering flow are known, the minimum possible external drag which must be incurred can be evaluated. The proportion between internal and external diffusion used in the inlet can be determined with the criterion of producing a drag of the same order as the minimum drag fixed by the ratio between diameter of the free-stream tube and the maximum diameter of the body.

**SYMBOLS**

- $D_b$: maximum diameter of central body
- $D_l$: diameter of cowling at lip
- $D_b/D_l$: ratio of maximum central-body diameter to diameter at cowling lip, termed herein “central-body-diameter parameter”
- $H_b$: total pressure of free stream
- $H_d$: total pressure after diffusion
- $H_b/H_0$: total-pressure recovery
- $M_b$: free-stream Mach number
- $M$: local Mach number
- $p_0$: free-stream static pressure
- $P$: local static pressure
- $P$: pressure coefficient, $P = P_0 - P_0$
- $q_0$: free-stream dynamic pressure
- $r_b$: radius of central body
- $r_i$: internal radius of cowling
- $r_e$: external radius of cowling
- $R$: radius of curvature of central-body fairing
- $x$: coordinate along center line of inlet configuration
- $e$: shock-wave angle
- $\eta$: kinetic-energy efficiency
- $\theta_e$: semiangle of cone of central body
- $\theta_i$: cowling-position efficiency (angle between axis of diffuser and line joining apex of cone to lip of cowling)
- $\theta_i^*$: cowling-position parameter for which conical shock wave coincides with lip of cowling
- $\theta_i$: cowling-position parameter for which the internal contraction ratio corresponds to the value given by one-dimensional theory as the maximum contraction ratio for which the internal diffuser starts at the Mach number at the entrance of the diffuser

**AERODYNAMIC CRITERIA USED IN THE DESIGN OF THE INLETS TESTED**

In order to obtain high pressure recovery in supersonic inlets, it is necessary to decelerate the air from the free-stream Mach number first to a low supersonic speed with small shock losses and then to subsonic speed with a shock near $M=1$. The diffusion of the supersonic stream can occur before the stream enters the inlet (external compression) or inside the inlet (internal compression). The external compression is produced by compression waves or shock waves, which are generated by the central body and tend to converge to form only one shock wave. This shock wave can extend beyond the stream tube which enters the inlet, so that a variation of momentum occurs in the external flow and, therefore, an external drag is produced. In the stream tube entering the inlet, the compression can be very nearly isentropic, and the external compression therefore becomes very efficient. The internal compression occurs without interference from the outside flow and therefore does not affect external drag. The maximum compression which can actually occur depends on the maximum possible contraction of the stream permitted by the starting conditions (ref. 2). Inlets with internal...

INVESTIGATION OF LOW-DRAG SUPERSONIC INLETS AT MACH NUMBERS OF 3.30, 2.75, AND 2.45

channel be designed with the criteria of permitting the existence of the shock AE (fig. 3(b)). The shock AE produced by the lip of the cowling can exist if the shape of the central body at E permits reflection of the shock AE. If the boundary-layer effect is neglected, this condition can be respected by selecting the lip angle and the shape of the body near E in such a manner that the Mach number and the direction of the flow at E permits the reflection of the shock. However, the presence of a well-developed boundary layer at E makes the problem more difficult. The reflection at E cannot be exactly determined by theoretical analysis. When the shock AE is strong and the boundary layer ahead of E has undergone a large positive pressure gradient, separation can occur behind the shock so that a reduction of the geometrical section and choking of the internal diffuser results. For this reason, especially when the chosen value of the external compression is small, it is often more convenient to obtain all the compression across a shock wave from the apex of the central body rather than across gradual compression waves produced along the surface OD, since the compression waves produce a positive pressure gradient that increases the thickness of the boundary layer. The possibility of the reflection can be assured by introducing a local expansion in front of the point of reflection E.

In figure 4 is shown the design of an inlet in which these criteria were used. The figure also gives the flow analysis obtained with the characteristics theory (ref. 5). The central body of the inlet has a semi cone angle of 25°, and for the design Mach number of 3.301 the shock generated by the nose is reflected at the lip of the cowling. The lip of the cowling has an internal inclination of 4° with respect to the free stream. The Mach number behind the conical shock is 2.308 and the deviation across the conical shock is 17°51′; therefore, the reflected wave corresponds to a deviation of 13°51′. The maximum possible deviation for a Mach number of 2.308 is of the order of 27°. The difference between maximum deviation of 27° and the deviation used at A is large because the inlet has been designed to have internal supersonic flow also for large angles of yaw for which the assurance of reflection of the shock from the lip at the surface of the central body becomes more critical. The maximum internal diameter of the cowling is 1.052 of the free-stream tube diameter.

The Mach number behind the reflected wave at the lip is 1.760. The reflected wave tends to become stronger near the axis; therefore, in order to permit reflection of the shock from the central body and to avoid too large an internal contraction ratio, an expansion is introduced along the central body which accelerates the flow along the surface. A throat of almost constant cross section was added in order to decrease the effect of separation behind the strong shock. By considering all shock losses, an average theoretical pressure recovery of 0.62 was obtained for this configuration. The experimental values can be expected to be near this value if boundary-layer separation is avoided. The boundary layer increases the actual internal contraction ratio, so that the efficiency of the internal supersonic compression is increased, but the losses due to the friction, which are not considered in this analysis, decrease the efficiency and tend to produce some instability in the flow. In order to eliminate this instability, the shock cannot be at the throat of the internal diffuser and, therefore, the efficiency of the supersonic compression decreases.

The external shock drag for this inlet has been determined analytically for the same Mach number. The external shape selected and the external shock configuration and pressure distribution are shown in figure 4. The ratio between the maximum external cross-sectional area and the entering free-stream-tube area is 1.167. The drag coefficient based on the maximum area of the cowling cross section is 0.0081 and becomes 0.0095 if the free-stream-tube area is used. The drag of the cowling is small in comparison with the drag of inlets with larger external compression. For example, for an inlet with very large external compression (diffuser no. 3, ref. 4), Oswaltitsch used a similar analysis and found for a Mach number of 2.9 an external drag coefficient of 0.43 when the maximum cross section of the inlet was considered and of 0.90 when the maximum free-stream tube area was considered. This inlet has a very high pressure recovery but a very high drag, especially if referred to the free-stream tube area, because the ratio between the area of the maximum cross section of the body to the free-stream-tube area is of the order of 2.1. This ratio cannot be much smaller since the deviation required at the lip is very large (of the order of 35°).

When the free-stream Mach number in front of the inlet shown in figure 4 is reduced and the internal contraction ratio becomes too large, a strong shock must be expected near the entrance of the inlet, as shown in figure 5. For this condition, the pressure recovery does not decrease greatly because the Mach number behind the conical shock is low, but the external drag increases. However, also in this case the external drag cannot be very large if the diameter of the free-stream tube of the cowling is not much less than the maximum possible diameter of the free-stream tube for the design condition because the external shock decreases in intensity very rapidly owing to the expansion around the cowling.

MODELS AND EXPERIMENTAL SYSTEM

In order to have some experimental values of pressure recovery which can be obtained with inlets of this kind, models with different geometrical parameters were constructed and tested in an intermittent-flow jet. For comparison, an inlet with very large external compression was also tested.

The general arrangement of the models tested is shown in figure 6. Each model has a central body supported by three equally spaced streamlined struts placed in the subsonic diffuser. The pressure recovery has been determined by nine total-pressure tubes which permitted a survey along two radii in the maximum cross section of the diffuser. The static pressure was also determined at two radii in the maximum cross section of the diffuser. The local Mach number at this section in which the pressure recovery was measured was of the order of 0.15 for \(M_0=3.30\) and 0.2 for \(M_0=2.45\).
Figure 4.—External and internal flow analysis of an inlet. (All dimensions are in inches.)
The average pressure recovery was obtained by the equation:

$$H_{ac} = \frac{1}{A} \int_{r_s}^{r_i} 2\pi p_{local} r \, dr$$

where $A$ is the area at the measuring plane, $r_s$ the radius of the central body, and $r_i$ the internal radius of the cowl. The back pressure was regulated during the tests by means of a movable plug which was placed on the end of the central body.

The test models were so designed that the shape of the cowl, the shape of the central body, and the position of the central body with respect to the cowl (given by the cowl-position parameter $\theta$) could be easily changed. The position of the central body was varied by moving it axially. Tests were made with the position of the central body fixed before the tests (constant-geometry diffuser) and a few tests were made in which the position of the central body was varied (and hence the internal-contraction ratio changed) during the tests (variable-geometry diffuser). This part of the investigation was not extensive because no gains in pressure recovery were obtained by varying the geometry at a fixed Mach number.

All the cowlings tested are shown in figure 7. Four cowl shapes were considered. Because no external drag measurements were considered in this series of tests, only the
lip angles and the internal cowling shapes were designed with aeroodynamic criteria. Three of the cowlings were designed so as to have internal and external lip angles, respectively, of 0° and 2°, 4° and 7°, and 7° and 10°. The actual shape of the 7°,10° cowling tested and given in figure 7 is slightly different from the original design. This difference, due to construction is localized at the lip and is small; therefore, the cowling was not rebuilt. The fourth cowling shown is that used in the inlet with large external compression and was built according to the design given in reference 4.

The central-body shapes used are shown in figure 8. The two fundamental parameters considered in the design of the central bodies were the semicone angle θ and the central-body-diameter parameter $D_b/D_l$. The cone angle fixes the intensity of the external compression, and the ratio $D_b/D_l$, together with the cowling-position parameter $e_l$, fixes the internal contraction ratio. The central body of the model with large external compression given in figure 8 (d) was derived (like that of the cowling) from the data in reference 4. The dimensions of the model discussed in reference 4 were not exactly given; therefore, tests were made for different cowling-position parameters.

The models were tested at three free-stream Mach numbers of 3.30, 2.75, and 2.45 at approximately zero angle of attack. Some values of internal contraction ratio as a function of cowling-position parameter $e_l$ for various central-body diameters were calculated in order to obtain an experimental check on the one-dimensional theory (ref. 2) for the starting conditions and are shown in figures 9 to 11. The internal contraction ratio has been calculated for a section perpendicular to the average direction of the stream in the zone considered. In figures 9 to 11, the starting contraction ratio given by one-dimensional theory has been indicated by horizontal lines. The corresponding value of the cowling-position parameter is called $e_l$. The cowling-position parameter $e_l$ that corresponds to the condition at which the conical shock is at the lip of the cowling has also been indicated by the vertical lines.

The models tested had a maximum diameter of approximately 1.83 inches, and the corresponding test Reynolds numbers referred to the maximum diameter were about $3.5 \times 10^6$ for $M_0=3.30$ and between 3 and $3.5 \times 10^6$ for Mach numbers of 2.45 and 2.75. This Reynolds number corresponds to that of a body having a diameter of 2.3 feet at an altitude of 70,000 feet. The test-section jet dimensions were approximately 3 inches by 4 inches. All tests were made in an open jet, with low-humidity air from a large pressurized tank. The pressure readings were recorded photographically from a precision pressure-gage manometer. The maximum possible errors of the measured values are estimated to be of the order of 1 percent.

Shadowgraphs of the flow were obtained for various combinations of central body and cowling and various positions of the central body with respect to the cowling.

INVESTIGATION OF LOW-DRAG SUPersonic INLETS AT MACH NUMBERS OF 3.30, 2.75, AND 2.45

ANALYSIS AND DISCUSSION OF THE RESULTS
THE MAXIMUM PRESSURE RECOVERY AS A FUNCTION OF THE COWLING POSITION PARAMETER

For every combination of cowling and central body considered, figures 12 to 23 give the maximum pressure recovery obtained for different cowling-position parameters for the three Mach numbers at which the tests were made. In order to distinguish the flow configurations for which the flow at the entrance is still supersonic from the configurations for which the flow at the entrance is subsonic (fig. 5), two different symbols have been used in all the figures. The circles indicate points corresponding to configurations having supersonic flow at the entrance of the diffuser, whereas the square symbols indicate points for which the flow in front of the inlet becomes subsonic. The second condition corresponds to a larger external drag. The existence of supersonic or subsonic flow at the entrance of the diffuser was determined by an analysis of the shadowgraphs of the flow taken during the tests.

In all the figures giving the value of the maximum pressure recovery as a function of the cowling-position parameter \( \theta \), two special values of \( \theta \) are indicated. They are \( \theta^* \) and \( \theta' \), previously defined. For values of \( \theta \) less than \( \theta^* \), the conical shock is ahead of the lip of the cowling; therefore, an additive drag exists because the free-stream-tube diameter corresponding to the internal flow is smaller than the diameter of the intake (ref. 1). This drag must be added to the external cowling pressure drag for determining the total drag. For values of \( \theta \) equal to or larger than \( \theta^* \) for points indicated by the circular symbols, the internal flow does not interfere with the external flow; therefore, the total drag is equal to the drag along the external surface of the cowling and is small.

The value of \( \theta^* \) indicates the position for which the starting conditions of the internal diffuser given by the one-dimensional theory are obtained. Therefore, for values of \( \theta \) larger than \( \theta^* \) and smaller than \( \theta' \), all external supersonic compression (square symbols) is predicted by the one-dimensional theory. The value of \( \theta' \) has been determined by using the average Mach number between the lip of the cowling and at the surface of the cone and, therefore, loses significance when the shock is inside the lip. In a few configurations expansion waves are produced in front of the entrance of the inlet by the central body. In the determination of the value of \( \theta' \), the expansion waves for these few cases have not been considered.

For all the tests if the mass flow was decreased somewhat below the maximum possible value by throttling in the rear of the diffuser, an unstable condition occurred and strong vibrations were found in the flow. These types of vibrations existed for all models tested when the flow was choked in the rear of the diffuser and have also been reported previously in references 3 and 4. The vibration or unstable condition corresponds to a fluctuation of the frontal shock and a variation of the internal mass flow. These vibrations do not exist if the flow at the entrance of the diffuser is subsonic because of starting conditions when the mass flow is the maximum possible but appear also in this case when the mass flow is decreased by a large amount. Some variation of Reynolds number does not affect the phenomenon of vibration.

The values of the maximum pressure recovery are plotted in figure 12 as a function of \( \frac{D_s}{D_i} \) for \( \theta = 20^\circ \) and the 4°,7° cowling. For \( \frac{D_s}{D_i} = 0.733 \) (fig. 12 (a)) the internal contraction ratio is small, and internal supersonic flow can therefore exist for all Mach numbers. Consequently, the external drag is small, and the additive drag is zero for \( \theta = 33^\circ \) or larger for all the test Mach numbers. If the diameter of the central body increases (figs. 12 (b) and 12 (c)), the pressure recovery increases until the internal contraction ratio becomes too large and all the supersonic compression is outside. The maximum pressure recovery obtained for this inlet configuration is about 0.71 for \( M_0 = 2.45 \), 0.63 for \( M_0 = 2.75 \), and 0.54 for \( M_0 = 3.30 \) for \( \frac{D_s}{D_i} = 0.834 \).
Figure 12.—Pressure recovery as a function of cowling-position parameter for $\theta_e = 20^\circ$ and 4°, 7° cowling.

(a) 4°, 7° cowling; $D_b/D_l = 0.733$; $\theta_e = 20^\circ$.

(b) 7°, 10° cowling; $D_b/D_l = 0.752; \theta_c = 30°$.  
**Figure 22.**—Continued.
The maximum pressure recovery obtained for the central body with $\theta_c = 22^\circ$ and the $7^\circ, 10^\circ$ cowlings for $D_b/D_i = 0.719, 0.752, 0.784, 0.817, \text{ and } 0.850$. Presented in figure 13. The results are similar to those obtained for the $4^\circ, 7^\circ$ cowlings. The maximum pressure recovery obtained for $M_0 = 3.30$ for $D_b/D_i = 0.850$ is 0.54 (fig. 13 (c)). The internal flow is supersonic for a contraction ratio slightly higher than the maximum contraction ratio considered by one-dimensional theory.

In figure 14 are presented some results for the configuration with $\theta_c = 22^\circ$ and the $0^\circ, 2^\circ$ cowlings for $D_b/D_i = 0.733$ and 0.767 at $M_0 = 2.45$. The contraction ratio of the configuration tested is larger than the contraction allowed by the starting conditions so that the diffusers do not start.

The maximum pressure recovery is plotted in figure 15 as a function of the cowlings-position parameter for the central body with $\theta_c = 22^\circ$ and the $4^\circ, 7^\circ$ cowlings for $D_b/D_i = 0.733, 0.767, 0.800, 0.834, \text{ and } 0.867$. The flow at the lip is supersonic for $D_b/D_i = 0.733$ and 0.767 (figs. 15 (a) and 15 (b)) for all test Mach numbers, and maximum-pressure-recovery values of 0.77, 0.64, and 0.42 are obtained for Mach numbers of 2.45, 2.75, and 3.30, respectively, with very low external drag. If the diameter of the central body increases, the maximum pressure recovery for higher Mach numbers increases, but the range of Mach numbers for which the flow at the lip is supersonic decreases. For $D_b/D_i = 0.800$ pressure-recovery values of 0.67 and 0.49 are obtained for Mach numbers of 2.75 and 3.30, respectively (fig. 15 (c)), whereas for $D_b/D_i = 0.834$ (fig. 15 (d)), the pressure recovery for $M_0 = 3.30$ is 0.56. If the mass flow is decreased by about 8 percent (fig. 15 (d)), a strong shock occurs in front of the lip of the diffuser and the pressure recovery decreases slightly. A further increase in the diameter (fig. 15 (e)) does not increase the pressure recovery.

Figure 16 gives the values of the maximum pressure recovery for a configuration with $\theta_c = 22^\circ$ and the $7^\circ, 10^\circ$ cowlings for central-body-diameter parameters $D_b/D_i$ of 0.719, 0.752, 0.784, 0.817, \text{ and } 0.850. For $D_b/D_i = 0.719, 0.752, \text{ and } 0.784$ (figs. 16 (a) to 16 (c)) the flow in front of the inlet can be supersonic for all Mach numbers considered. For $D_b/D_i = 0.784$ for supersonic flow at the entrance, maximum-pressure-recovery values of 0.75, 0.67, and 0.45 are obtained for Mach numbers of 2.45, 2.75, and 3.30, respectively (fig. 16 (c)); whereas for $D_b/D_i = 0.850$ (fig. 16 (c)), a maximum pressure recovery of 0.57 is obtained for $M_0 = 3.30$. The pressure recovery $M_0 = 2.45$ for $D_b/D_i = 0.850$ is less than for $D_b/D_i = 0.752$ (fig. 16 (b)); the flow in front of the inlet is subsonic in both cases, but for $D_b/D_i = 0.850$, $\theta_c$ is far from $\theta_c^*$ and, therefore, some expansion waves are produced by the central body in front of the lip.

Figures 16 (a), 16 (b), 16 (d), and 16 (e) also give some values of pressure recovery for reduced mass flow of the order of 9 percent. For $D_b/D_i = 0.752$ and $M_0 = 2.45$ (fig. 16 (b)) the
maximum pressure recovery is obtained when the mass flow is reduced and the normal shock is ahead of the cowling lip. These and similar data obtained in all the tests show that the losses due to boundary layer and the necessity of internal flow-stability have a significant effect on the pressure recovery. Practically, it is not possible by increasing the back pressure to put the normal shock near the throat, but it is necessary to have supersonic flow to some extent in the divergent part of the diffuser. Tests have been made without varying the back pressure after the internal diffuser has started for inlets having high internal contraction ratios. The maximum pressure recovery that can be obtained in this condition for a Mach number of 3.3 is only slightly less (of the order of 2 or 3 percent) than the maximum that can practically be obtained by increasing the back pressure after the diffuser has started, whereas the theoretical gain is of the order of 10 percent or larger. The data shown in figures 16 (a), 16 (b), and 16 (c) confirm these results. The results for a central body with \( \theta = 25^\circ \) and \( 0^\circ, 2^\circ \) cowling for \( \frac{D_b}{D_i} = 0.733, 0.767, \) and 0.800 are shown in figure 17. The flow is supersonic in front of the diffuser for all Mach numbers and cowling-position parameters tested because the flow deviation across the shock is very large (18° for \( M_b = 3.3 \)) and the shock from the lip cannot be reflected at the surface of the central body. Figure 18 gives the results for \( \theta = 25^\circ \) and \( 4^\circ, 7^\circ \) cowling for \( \frac{D_b}{D_i} = 0.733, 0.767, 0.800, 0.834, 0.847, \) and 0.867. For \( \frac{D_b}{D_i} = 0.733 \) and \( M_b = 2.45 \) the entering flow is supersonic in the region of \( \theta = \theta_s^* \). For larger values of \( D_b/D_i \) the entering flow is supersonic only for values of \( \theta \) much lower than \( \theta_s^* \). The maximum pressure recovery for supersonic entrance flow is 0.76 (figs. 18 (a) and 18 (b)), whereas for subsonic entrance flow a value of 0.80 is obtained (figs. 18 (c) and 18 (d)). For \( M_b = 2.75 \) the maximum pressure recovery of 0.67 occurs with supersonic flow in front of the inlet for \( \frac{D_b}{D_i} = 0.867 \) (fig. 18 (f)), whereas with supersonic flow at the entrance the maximum pressure recovery of 0.64 is for \( \frac{D_b}{D_i} = 0.800 \) (fig. 18 (e)). For \( \frac{D_b}{D_i} = 0.847 \) (fig. 18 (e)) the supercritical condition has not been determined. For a central body with \( \theta = 25^\circ \) and the \( 7^\circ, 10^\circ \) cowling, results are presented in figure 19 for \( \frac{D_b}{D_i} = 0.719, 0.752, 0.784, 0.817, 0.830, \) and 0.850. For \( \frac{D_b}{D_i} = 0.719 \) and supersonic flow at the entrance, a pressure recovery of 0.78, 0.60, and 0.42 has been obtained for \( M_b = 2.45, 2.75, \) and 3.30, respectively. At a Mach number of 2.75 and for \( \frac{D_b}{D_i} = 0.752 \) and 0.784 (figs. 19 (b) and 19 (c)), the pressure recovery is larger for subsonic flow in front of the inlet than for supersonic flow in front of the inlet. For \( \frac{D_b}{D_i} = 0.817 \) (fig. 19 (d)) the maximum pressure recovery at \( M_b = 3.30 \) is 0.53. When the mass flow is decreased, the shock moves ahead of the lip and the recovery drops to 0.51. As was previously explained, for all cases in which reduced-mass-flow data are given, the reduction of mass flow must be small and of the order of 10 percent. For larger variations of mass flow, unsteady flow conditions have been found. In figure 20 are given the results for a central body with \( \theta = 30^\circ \), the \( 0^\circ, 2^\circ \) cowling, and \( \frac{D_b}{D_i} = 0.767 \) and 0.800 for \( M_b = 2.45 \). For these conditions the flow in front of the inlet is subsonic. The contraction ratio is greater than the starting contraction ratio. The values of pressure recovery for a configuration with \( \theta = 30^\circ \) and the \( 4^\circ, 7^\circ \) cowling for \( \frac{D_b}{D_i} = 0.733, 0.767, \) and 0.800 are given in figure 21. For Mach numbers of 2.45 and 2.75 the reflection of the shock inside the inlet cannot occur and, therefore, the flow in front of the inlet is supersonic. The reflection can occur for \( M_b = 3.30 \). The maximum pressure recovery obtained for \( M_b = 2.45 \) is 0.82 and the maximum recovery for \( M_b = 3.30 \) is 0.46 (fig. 21 (c)). The results obtained for the central body with \( \theta = 30^\circ \) and the \( 7^\circ, 10^\circ \) cowling are given in figure 22 for \( \frac{D_b}{D_i} = 0.719, 0.752, \) and 0.784. Because of the smaller intensity of the reflected shock at the lip of the cowling, the inlet can have internal supersonic flow for \( M_b = 2.75 \) (fig. 22 (b)). At this Mach number the pressure recovery is higher with supersonic flow at the entrance. Figure 23 shows the maximum pressure recovery as a function of the cowling-position parameter for the inlet with large external compression. The maximum pressure recoveries obtained are 0.84, 0.72, and 0.54 for \( M = 2.45, 2.75, \) and 3.30, respectively.

The analysis of all the curves shows that for \( \theta \) larger than \( \theta_s \) and smaller than \( \theta_s^* \) the flow in front of the inlet usually becomes subsonic in agreement with one-dimensional theory. (See figs. 12 (b), 12 (c), 13 (b), 13 (c), 15 (b) to 15 (e), 16 (c) to 16 (e), 18 (b) to 18 (d), and 18 (f).) Only in a few cases has a higher contraction ratio than that given by one-dimensional theory been found. See, for example, figures 12 (b) \( (M_b = 2.75) \), 13 (c) \( (M_b = 3.30) \), 15 (c) \( (M_b = 2.75) \), 15 (d) \( (M_b = 2.75) \), and 15 (e) \( (M_b = 3.30) \). The differences are very small and can be justified by the accuracy of determining the stream-tube areas and the Mach number in front of the entrance. For example, the increase in Mach number due to the expansion waves from the central body has not been considered. For some configurations, subsonic flow in front of the entrance has been found when the contraction ratio is less than the starting contraction ratio. In these cases, subsonic flow is due to the impossibility of reflecting the conical field at the lip of the cowling or at the surface of the central body, as was previously discussed. For example, for the inlet with \( \theta = 25^\circ \) and the \( 0^\circ, 2^\circ \) cowling (fig. 17) for Mach numbers of 2.45, 2.75, and 3.30, the reflection of the shock is not possible. Another example is given by the data in figure 19. The diffuser starts at \( M_b = 2.45, 2.75, \) and 3.30 for \( \frac{D_b}{D_i} = 0.719, \)
0.752, and 0.784, while subsonic flow occurs in the zone of \( \theta_1 \) for \( D_b/D_i = 0.817, 0.830 \), and 0.850. For these large central-body diameters the diffuser starts for lower values of \( \theta_1 \). This result can be explained by the following consideration. For larger values of \( D_b/D_i \), the Mach number and the direction of the stream in front of the inlet, so that the possibility of reflection is increased. The pressure recovery obtained when the flow in front of the lip is subsonic is in some cases larger than the maximum calculated theoretically on the basis of compression across the conical shock and a normal shock in front of the cowling. This result is unexpected because the subsonic diffuser also produces some losses. Shadowgraphs of the phenomena, discussed subsequently, give an explanation of these results. The compression in front of the inlet occurs across a lambda shock produced by the boundary layer at the surface of the cone. Therefore, the shock losses for the compression in front of the inlet are much smaller than across a single normal shock. For supersonic flow in front of the inlet the maximum pressure recovery increases when \( \theta_1 \) increases because the internal contraction ratio increases. When \( \theta_1 \) is larger than \( \theta_1^* \), the conical shock enters the inlet and expansion waves are produced locally at the lip of the cowling; therefore the increase of \( \theta_1 \) produces an increase of Mach number in front of the inlet together with an increase in contraction ratio. The two variations have opposite effects on pressure recovery; therefore increasing \( \theta_1 \) beyond \( \theta_1^* \) can provide either an increase or a decrease in pressure recovery. For subsonic flow in front of the inlet when \( \theta_1 \) increases, the pressure recovery tends to decrease because the normal shock moves in the direction of the apex of the cone.

A few tests of a variable-geometry inlet were made by moving the position of the central body after supersonic flow into the inlet had been established. With the conical shock ahead of the lip, the change in position of the central body permitted a variation of the internal contraction ratio because the diameter of the entering stream tube, and therefore the internal contraction ratio, changed. Tests were performed for inlets of cone semiangles of 20°, 22°, and 25° and the \( 4°, 7° \) and \( 7°, 10° \) cowlings at Mach numbers of 2.45 and 3.30 for different central-body diameters. No difference in the value of the maximum pressure recovery was found. The impossibility of obtaining higher pressure recovery with this scheme can be attributed to the disturbances in the subsonic region, which fixes the value of the minimum Mach number that is practical in the divergent region of the diffuser in order to have stable conditions. However, the possibility of a small regulation of the position of the central body can be very important in practical applications for two reasons.

The motion of the central body permits the changing of the internal contraction ratio and therefore permits the use of the best possible configuration at every Mach number. The best configuration is the configuration of minimum drag and highest pressure recovery. For example, in figure 16 (e) the optimum \( \theta_1 \) for \( M_o = 3.30 \) is about 31°, whereas for \( M_o = 2.45 \) and 2.75 the optimum \( \theta_1 \) is about 29°.

For a given Mach number a movement of the central body permits a regulation of the dimension of the internal streamtube diameter and thus permits supersonic flow at the entrance also for reduced mass flow. For example, from figure 19 (f), at \( M_o = 3.30 \), changing \( \theta_1 \) from 33.4° to 31.5° permits a 14-percent reduction in mass flow to be obtained with internal supersonic flow. The motion of the central body would be 0.015 times the diameter of the cowling. Such a regulation of mass flow can be very useful in order to meet desired flight requirements. Some of the configurations have been tested at small angles of attack (1° and 2°) and no changes have been found in the values of pressure recovery.

**THE EFFECT OF THE CONE-ANGLE PARAMETER ON THE MAXIMUM PRESSURE RECOVERY OBTAINED**

Figures 12 to 22 give the maximum pressure recovery obtained for the Mach numbers considered for every central-body diameter and cowling tested. The highest maximum values obtained for given values of \( D_b/D_i \), Mach number, and cowling have been plotted in figures 24 to 26 as a function of the cone semiangle. (For purposes of clarity, a distinction is necessary in the use of the term “maximum,” since all pressure recoveries are maximum values for the configurations tested. Hereinafter, therefore, the term “highest pressure recovery” refers to the highest maximum value.) Every point on the curves corresponds to a different cowling-position parameter, the value of which can be determined from figures 12 to 22.

Figure 24 gives the value of the highest pressure recovery obtained as a function of the cone semiangle for a Mach number of 3.30 for the \( 4°, 7° \) and \( 7°, 10° \) cowlings. A maximum pressure recovery of 0.56 has been obtained for \( \theta_c = 22° \) and \( D_b/D_i = 0.834 \) for the \( 4°, 7° \) cowling (fig. 24(a)).

For this condition \( \theta_1 \) is larger than \( \theta_1^* \); therefore, the external drag is low. If the value of \( D_b/D_i \), decreases, the maximum internal contraction decreases and, therefore, the value of the highest pressure recovery for a given cone angle decreases. The maximum value of pressure recovery for low values of \( D_b/D_i \) increases as the cone angle increases. This variation is logical because as the value of \( \theta_1 \) increases the Mach number at the inlet decreases and the contraction ratio required in order to obtain high recovery decreases. The highest pressure recovery is obtained for a cone semiangle of about 22°. The corresponding internal contraction ratio is the maximum value of contraction ratio permitted by the starting conditions (fig. 10(b)). If the inclination of the cowling-lip angles
is increased, the shapes of the curves are not greatly affected.

The values of highest pressure recovery obtained as a function of the cone semiangle for a Mach number of 2.75 for the 4°, 7° and 7°, 10° cowlings are shown in figures 25 (a) and 25 (b) for supersonic entrance flow and in figures 25 (c) and 25 (d) for subsonic entrance flow. Figure 25 (a) gives the highest pressure recovery obtained (0.67) for supersonic entrance flow for the 4°, 7° cowning. The value occurs for $\theta_c=22^\circ$ at an internal contraction ratio near the maximum possible for the starting conditions. Figure 25 (b) gives similar results for the 7°, 10° cowning. Figure 25 (c) gives the values of highest pressure recovery obtained as a function of the cone semiangle for the 4°, 7° cowning with subsonic entrance flow. The highest pressure recovery obtained is 0.68 for $\theta_c=22^\circ$ for $D_b/D_l$ of 0.834 and $\theta_c=30^\circ$ for $D_b/D_l$ of 0.860. Figure 25 (d) shows results similar to figure 25 (c) for the 7°, 10° cowning. The highest pressure recovery obtained is of the order of 0.69 for $D_b/D_l$ of 0.850 and $\theta_c=25^\circ$.

Figures 26 (a) and 26 (b) give the values of highest pressure recovery obtained at $M_0=2.45$ as a function of the cone semiangle for different body-diameter parameters for the 4°, 7° and 7°, 10° cowlings with supersonic entrance flow. The maximum highest pressure recovery obtained for the 4°, 7° cowning is 0.77 for $\theta_c=23^\circ$. For the 7°, 10° cowning the maximum highest pressure recovery of 0.78 is obtained for $\theta_c=25^\circ$. For $\theta_c=30^\circ$ supersonic flow at the entrance is not possible. Possibly slightly higher values of pressure recovery could be obtained for $\theta_c=26^\circ$ to $27^\circ$. The results show that the optimum cone semiangle decreases slightly when the Mach number increases and, in the range of Mach numbers considered, is in the range of 22° to 25° for supersonic entrance flow. Figures 26 (c) and 26 (d) give the highest pressure recovery obtained with subsonic flow at the entrance. A pressure recovery of 0.82 has been obtained for $\theta_c=30^\circ$ with the 4°, 7° cowning and of 0.80 for $\theta_c=25^\circ$ with the 4°, 7° and 7°, 10° cownings.

HIGHEST PRESSURE RECOVERY OBTAINED AS A FUNCTION OF THE CENTRAL-BODY-DIAMETER PARAMETER

The data from figures 12 to 22 have been cross-plotted and, for a specific Mach number, the highest pressure recovery obtained for every semiangle and cowning combination has been plotted as a function of the central-body-diameter parameter (figs. 27 to 32). Figures 27 to 32 give...
the highest pressure recovery for a specific Mach number and, in addition, for the same cowling-position parameters obtained for the specific Mach number considered, the maximum pressure recovery (not necessarily the highest) for the other Mach numbers of the tests. The points indicated in the figures are not necessarily experimental points, but the square and circle symbols are still used in order to distinguish the conditions for which the flow is supersonic at the entrance of the diffuser (circle symbols) from the conditions for which the flow at the entrance is subsonic (square symbols). In the figures the central-body-diameter parameter for which the conical shock is at the lip of the cowling \( \theta_i = \theta_i^* \) is again shown by the vertical mark. The relative position of \( \theta_i \) with respect to \( \theta_i^* \) is also indicated. For values of the central-body parameter equal to or less than this value, the conical shock is inside the cowling and, therefore, the external drag is small and the internal mass flow is the maximum possible because the free-stream tube that enters the cowling is equal to the cross section of the entrance of the inlet. When \( D_b/D_i \) is larger than the value corresponding to \( \theta_i^* \), the conical shock is in front of the lip and, therefore, the external drag is larger because an additive drag exists (ref. 1), and the mass flow is less than the maximum possible for the entrance cross section considered. The entering mass flow for the supersonic entrance conditions can be easily determined from the analysis of conical flow.

Figure 27 gives the highest pressure recovery obtained at a Mach number of 3.30 as a function of the central-body-diameter parameter for the \( 4^\circ,7^\circ \) cowling and semicone angles of \( 20^\circ, 22^\circ, 25^\circ \), and \( 30^\circ \). For \( M_0 = 3.30 \) and the \( 20^\circ \) or \( 22^\circ \) cones, a maximum value of pressure recovery of 0.56 is obtained for \( D_b/D_i = 0.84 \), which corresponds to the value for \( \theta_i^* \).

When the value of \( D_b/D_i \) decreases, the pressure recovery decreases. For lower Mach numbers, however, supersonic flow can be established in the diffuser at values of \( D_b/D_i < 0.84 \). Similar results for the \( 7^\circ,10^\circ \) cowling are shown in figure 28. For this cowling the maximum pressure recovery also occurs around values of \( D_b/D_i = 0.84 \).

Figure 29 gives the highest pressure recovery obtained as a function of the central-body-diameter parameter at a Mach number of 2.75 for the \( 4^\circ,7^\circ \) cowling and for \( \theta_i = 20^\circ, 22^\circ \), and
INVESTIGATION OF LOW-DRAG SUPersonic INLETS AT MACH NUMBERS OF 3.30, 2.75, AND 2.45

25°. For \( \frac{D_b}{D_i} = 0.80 \) and \( \theta_c = 22° \), a pressure recovery of 0.67 is obtained with low external drag, since this value of \( D_b/D_i \) corresponds to \( \theta^*_i \) for this Mach number. At a Mach number of 3.30 for the same configuration, the pressure recovery is 0.50 (fig. 29 (b)). Similar results at a Mach number of 2.75 for the 7°,10° cowlings are given in figure 30. At a Mach number of 2.75 and \( \theta_c = 22° \), a pressure recovery of 0.68 is obtained for \( \frac{D_b}{D_i} = 0.80 \) and at a Mach number of 3.30 the pressure recovery for the same configuration becomes 0.50.

A similar analysis has been made for a Mach number of 2.45. Figure 31 gives the highest pressure recovery obtained as a function of the central-body-diameter parameter for the 4°,7° cowlings and semicone angles of 20°, 22°, 25°, and 30°. For \( \theta_c = 22° \) and \( \frac{D_b}{D_i} = 0.77 \), the pressure recovery for \( M_o = 2.45 \) is 0.77 and the corresponding recoveries at \( M_o = 2.75 \) and 3.30 are 0.65 and 0.47, respectively, with very low external drag. With subsonic flow in front of the inlet for \( \frac{D_b}{D_i} = 0.80 \), pressure recoveries of 0.80 and 0.82 have been obtained with semicone angles of 25° and 30°, respectively.

Figure 32 gives similar results for the 7°,10° cowlings for semicone angles of 20°, 25°, and 30° at a Mach number of 2.45. At \( \frac{D_b}{D_i} = 0.80 \) and supersonic entrance flow, pressure recoveries of 0.77, 0.67, and 0.51 have been obtained for Mach numbers of 2.45, 2.75, and 3.30, respectively.

MAXIMUM PRESSURE RECOVERY AS A FUNCTION OF MACH NUMBER

A typical variation of pressure recovery as a function of Mach number for a constant-geometry inlet is shown in figure 33. The typical configuration has a semicone angle of 22°, the 4°,7° cowlings, \( \frac{D_b}{D_i} = 0.834 \), and \( \theta_c = 32.2° \). Part of the curve corresponds to subsonic flow in front of the inlet and part of the curve corresponds to supersonic flow in front of the inlet.

The highest values of pressure recovery obtained from all the configurations tested are shown in figure 34. For comparison the pressure recovery for the inlet with all internal compression (ref. 2) is also shown.

Figure 35 gives the optimum values of kinetic energy
FIGURE 26.—Highest pressure recovery obtained as a function of cone semiangle for various central-body-diameter parameters for $M_b = 2.45$.

recovery of all the configurations tested and of the diffuser reported in reference 2. The values have been calculated by using the information in figure 34 and the expression (ref. 2):

$$\eta = 1 - \frac{5}{M_b^3} \left[ \frac{H_b}{H_e} \right]^{\frac{1}{3}} - 1$$

OPTICAL OBSERVATIONS OF THE FLOW PHENOMENA ABOUT THE INLETS

The shadowgraphs taken for every test point give a further indication of the flow phenomena about an inlet. Thus, a comparative analysis of the external drag of the different configurations can be made. In figures 36 to 39 some shadowgraphs for the configurations tested are shown.

Figure 36 gives the shadowgraphs for $\theta = 25^\circ$, the $7^\circ, 10^\circ$ cowling, and $D_s/D_t = 0.817$ for different values of $\theta_t$ at the condition of maximum pressure recovery for $M = 3.30$. The shadowgraph in figure 36(a) for $\theta_t = 31^\circ$ shows supersonic flow at the entrance, whereas figure 36(b) for the same $\theta_t$ shows subsonic flow at the entrance with reduced mass flow (fig. 19 (d)). The differences in the curvature of the external shocks in the external flow indicates that the drag is large for subsonic entrance-flow conditions. When $\theta_t$ becomes $34.1^\circ$, the conical shock enters the cowling and the external drag becomes very small. Figure 36(d) corresponds to a $\theta_t$ of $35.4^\circ$ with the conical shock still farther in the inlet. Figures 36(e) and 36(f) correspond to a $\theta_t$ of $35.9^\circ$. Both shadowgraphs show a strong shock in front of the lip. Figure 36(d) corresponds to the maximum possible mass flow in the inlet, whereas figure 36(e) corresponds to a slightly reduced mass flow, before the flow vibrations start. When the mass flow is reduced, the strong shock increases in intensity (fig. 36(f)). Figures 36(g) and 36(h) show similar results for $\theta_t = 36.6^\circ$. The shadowgraphs in figures 36(b), 36(f), 36(g), and 36(h) show the existence of the lambda shock at the surface of the cone.

Figure 37 shows the shadowgraphs at a Mach number of 2.75 for $\theta = 20^\circ$, the $7^\circ, 10^\circ$ cowling, and $D_s/D_t = 0.817$ for dif-

Different values of θι at the condition of maximum pressure recovery. The tests were made at a 1° angle of attack. The corresponding values of pressure recovery as a function of the cowling-position parameter are given in figure 13 (b). Figures 37 (a) to 37 (e) correspond to conditions where the flow at the entrance is supersonic. Figure 37 (f) corresponds to a θι of 29.9° for which subsonic flow exists in front of the inlet. The strong compression in front of the inlet produces a separation at the surface of the central body and, therefore, the shock near the surface appears as a lambda shock. The separation is visible in the shadowgraph.

Figure 38 shows the shadowgraphs at a Mach number of 2.45 for θι = 22°, the 7°, 10° cowling, and Dι/Gr = 0.752 for different values of θι and at an angle of attack of 2°. The corresponding values of pressure recovery are given in figure 16 (b) for zero angle of attack. For a 2° angle of attack the values of pressure recovery do not change. Figure 38 (b) corresponds to θι = 35.7° and supersonic flow at the entrance, whereas figure 38 (e) corresponds to the same θι but with a reduced mass flow. The photograph shows that when the flow into the inlet is subsonic, the flow phenomena are strongly dissymmetrical with respect to the axis of the inlet. This large dissymmetry of the flow always occurs for subsonic entrance flow when a small geometric dissymmetry exists. This discontinuity produces a variation of external aerodynamic properties of the body and the variations occur discontinuously when the strong shock jumps in front of the inlet. In order to avoid discontinuities of the internal and external aerodynamic characteristics of the inlet, the inlet must be designed in such a manner that supersonic internal flow can be maintained over all the range of possible angles of attack. Figure 38 (d) corresponds to a θι = 34.4° and supersonic flow at the entrance, whereas figures 38 (e) and 38 (f) correspond to a θι of 35.1° with supersonic and subsonic flow at the entrance, respectively. The pressure recovery for the condition of subsonic flow at the entrance shown in figure 38 (f) is larger than for the condition shown in figure 38 (e); however, as can be seen by the shock configuration, the external drag is larger for the condition of subsonic flow. In figure 38 (f) the lambda shock and the separation of the flow from the upper surface can be seen.

Figure 34.—Optimum pressure recovery obtained from all configurations tested.
Figures 39 (a) to 39 (d) present some shadowgraphs for the inlet with large external compression at a Mach number of 3.30 and different values of $\theta_t$ and at a Mach number of 2.75 and $\theta_t=30.5^\circ$. The pressure recovery data for this configuration are presented in figure 23. For comparison figures 39 (e) to 39 (h) show shock configurations for inlets designed for low external compression and having supersonic or subsonic flow at the entrance. Figure 39 (a) corresponds to a cowling-position parameter of 28.9° and a maximum pressure recovery of 0.49. Figure 39 (b) corresponds to a cowling-position parameter of 30° and a maximum pressure recovery of 0.54. Figure 39 (c) corresponds to a cowling-position parameter of 30.3° and a pressure recovery of 0.54. From an analysis of the three photographs it can be seen that the compression is more efficient in figure 39 (a); however, the pressure recovery, because of the presence of the boundary layer, is less than the maximum value obtained when all the supersonic compression occurs in front of the second deviation on the central body. All the results of these tests show that the phenomena in the boundary layer are of fundamental importance in the design of supersonic diffusers. The formation of lambda shock seems to increase the value of the pressure recovery if the separation following the shock is small. When the lambda shock is followed by large separation and the wake fills a large part of the entrance region, the pressure recovery decreases. The boundary-layer separation is also related to the fluctuation of the subsonic stream. These fluctuations are very important from a consideration of stability of flow, because a shock of some strength is required in order to have stability. This shock limits the value of the maximum pressure recovery that can be obtained for a given Mach number. Figure 39 (d) is the shadowgraph at a Mach number of 2.75 and $\theta_t=30.5^\circ$.

Figure 39 (e) is a shadowgraph for comparing the flow configuration for an inlet having a semicone angle of 22°, with the corresponding values of pressure recovery are given in fig. 19 (d).
INVESTIGATION OF LOW-DRAG SUPERSONIC INLETS AT MACH NUMBERS OF 3.30, 2.75, AND 2.45

7°, 10° cowl, \( \theta_i = 31.4° \), and \( \frac{D_h}{D_i} = 0.85 \), and a pressure recovery of 0.56, with the flow phenomena of figures 39 (a) to 39 (c). Figure 39 (f) is a shadowgraph of an inlet with \( \theta_i = 20° \), the 4°.7° cowl, and \( \frac{D_h}{D_i} = 0.867 \) for a Mach number of 3.30. The pressure recovery is 0.53. A shadowgraph for the same cowl and central body combination but \( \theta_i = 30° \) is shown in figure 39 (g). For this configuration the pressure recovery is 0.51 (fig. 12 (c)). In figures 39 (f) and 39 (g) the lambda shock is clearly shown. Figure 39 (h) shows a shadowgraph at \( M_e = 2.75 \) for the inlet having a semicone angle of 22°, the 4°.7° cowl, \( D_h/D_i = 0.800 \) and \( \theta_i = 32.9° \). The pressure recovery for this configuration is 0.67.

From the analysis of the shadowgraphs some indication for explaining the phenomena of vibration can be obtained. The vibrations occur only when the flow in the internal part of the diffuser is all subsonic. For this condition the disturbances from the subsonic part can be transmitted upstream. The vibrations occur when separation produced by the strong shock in front of the inlet exists at the surface of the one. Any variation of the position of the point of separation changes the position of the shock in front of the inlet and the dimension of the wake at the entrance of the diffuser and, therefore, the mass flow entering the inlet. To a variation of mass flow there corresponds a variation of back pressure at the end of the diffuser which is transmitted upstream and thus produces a vibration. The intensity of the vibration seems to depend upon the intensity of the separation and does not exist if the separation is very small. The vibrations seem to be reduced if the position of the point at which the separation begins is fixed by the geometrical construction of the inlet.

CONCLUSIONS

From the analysis of the aerodynamic criteria of the design of supersonic inlets and from the analysis of the experimental results, the following conclusions can be obtained:

1. The inlets with external compression permit a larger pressure recovery than the inlets with all internal compression. For practical problems at low free-stream Mach numbers (of the order of 1.4 to 2.0) the supersonic compression can be obtained entirely outside the inlet without a large increase in external drag. For free-stream Mach numbers of the order of 3.0, in practical problems, the maximum

![Figures 37 and 39](image-url)

**Figure 37.** Shadowgraphs of inlet configuration for \( \theta_i = 20° \), the 7°, 10° cowl, and \( D_h/D_i = 0.817 \) for different values of \( \theta_i \) for \( M_e = 2.75 \).

(The corresponding values of pressure recovery are given in fig. 13 (b).)
cross section of the body which contains the inlet can be of the same order of magnitude as the cross section of the free-stream tube used for the internal flow. In this case the use of all external compression produces a very large increase of external drag and the increase in efficiency obtained is not justified when the external drag is considered.

2. A practical solution requires a good compromise between the increase of pressure recovery and the increase of external drag due to the external compression. When the external compression is reduced and the free-stream Mach number is large, it is convenient to use an internal supersonic diffuser in order to increase the pressure recovery. With a good combination of external and internal supersonic compression, pressure recoveries of the order of those obtained with very large external compression have been obtained. In this case, the corresponding external drag is reduced.

3. The maximum possible contraction ratio in order to start the internal supersonic diffuser has been found to correspond essentially to the value given by one-dimensional theory. The increase of the value of the internal contraction ratio obtained by using variable geometry does not increase the pressure recovery, because of the disturbances from the subsonic diffuser. An increase in contraction ratio does not correspond to an increase in pressure recovery, because the Mach number at which the flow in the divergent diffuser passes from supersonic to subsonic Mach numbers is not fixed by the Mach number at the minimum section but is fixed by stability criteria. Also for constant geometry, the shock occurs at somewhat higher Mach numbers than that at the throat. The tests have shown that supersonic flow can be established inside the inlet if the contraction ratio is fixed by a consideration of the starting conditions and if the shape of the channel permits reflection of the shock both from the lip and from the surface of the central body.

4. Experimental results show that the boundary layer along the surface of the central body has a large influence on the value of the pressure recovery which can be obtained. At high Mach numbers, if a strong compression occurs along the surface of the central body, a separation can be produced which reduces the pressure recovery gain expected by a large external compression.

5. On the basis of the constant-geometry configurations analyzed, unstable conditions have been found in the flow, when the internal mass flow was reduced somewhat from the

---

Figure 38.—Shadowgraphs of inlet configuration for \( \theta_l = 22^\circ \), the \( 7^\circ, 10^\circ \) cowlings, and \( D_1/D_2 = 0.752 \) for different values of \( \theta_l \) for \( M_\infty = 2.45 \). (The corresponding values of pressure recovery are given in fig. 16 (b).)
maximum value possible. In order to avoid flow discontinuities, the inlets must be designed to have entering supersonic flow for the range of angles of attack to be used.

6. For a Mach number of 3.30 a pressure recovery of 0.57 has been obtained with a configuration having very low external drag. At Mach numbers of 2.45 and 2.75, maximum pressure recoveries of 0.78 and 0.67, respectively, have been obtained with the configurations having low external drag as compared with 0.84 and 0.72, respectively, with configurations having high external drag.
