### 2. GENERAL SYMBOLS

- \( W \), Weight = \( mg \)
- \( g \), Standard acceleration of gravity = \( 9.80665 \text{ m/s}^2 \) or \( 32.174 \text{ ft./sec.}^2 \)
- \( m \), Mass = \( \frac{W}{g} \)
- \( I \), Moment of inertia = \( mk^2 \). (Indicate axis of radius of gyration \( k \) by proper subscript.)
- \( \mu \), Coefficient of viscosity

### 3. AERODYNAMIC SYMBOLS

- \( S \), Area
- \( S_w \), Area of wing
- \( G \), Gap
- \( b \), Span
- \( c \), Chord
- \( b^2 \), Aspect ratio
- \( S' \), True air speed
- \( q \), Dynamic pressure = \( \frac{1}{2} \rho V^2 \)
- \( L \), Lift, absolute coefficient \( C_L = \frac{L}{qS} \)
- \( D \), Drag, absolute coefficient \( C_D = \frac{D}{qS} \)
- \( D_0 \), Profile drag, absolute coefficient \( C_{D_0} = \frac{D_0}{qS} \)
- \( D_i \), Induced drag, absolute coefficient \( C_{D_i} = \frac{D_i}{qS} \)
- \( D_p \), Parasite drag, absolute coefficient \( C_{D_p} = \frac{D_p}{qS} \)
- \( C_i \), Cross-wind force, absolute coefficient \( C_i = \frac{C_i}{qS} \)
- \( R \), Resultant force

### Additional Notes

- \( \nu \), Kinematic viscosity
- \( \rho \), Density (mass per unit volume)
- \( \rho \), Standard density of dry air, \( 0.12457 \text{ kg-m}^{-1}\text{s}^{-2} \) at \( 15^\circ \text{C} \) and 760 mm; or \( 0.002378 \text{ lb.-ft.}^{-1}\text{sec.}^2 \)
- \( \rho \), Specific weight of “standard” air, \( 1.2255 \text{ kg/m}^3 \) or \( 0.07651 \text{ lb./cu. ft.} \)

### Reynolds Number

\[ \frac{Vl}{\nu} \]

Reynolds Number, where \( l \) is a linear dimension (e.g., for a model airfoil 3 in. chord, 100 m.p.h. normal pressure at \( 15^\circ \text{C} \), the corresponding number is 234,000; or for a model of 10 cm chord, 40 m.p.s., the corresponding number is 274,000)

### Center-of-pressure coefficient

\( C_r \), Center-of-pressure coefficient (ratio of distance of c.p. from leading edge to chord length)

SUMMARY

The fundamental action of shear deformation of the flanges is discussed on the basis of simplifying assumptions. The theory is developed to the point of giving analytical solutions for simple cases of beams and of skin-stringer panels under axial load. Strain-gage tests on a tension panel and on a beam corresponding to these simple cases are described and the results are compared with analytical results. For wing beams, an approximate method of applying the theory is given. As an alternative, the construction of a mechanical analyzer is advocated.

INTRODUCTION

The so-called “semimonocoque” type of construction, which has been favored by aircraft designers for some time, presents serious difficulties in stress analysis. Static tests have proved that the bending action of such a structure is not always described with sufficient accuracy by the standard engineering formulas based on the assumption that plane cross sections remain plane. It will be necessary, therefore, to devise new working theories for the action of semimonocoque beams under bending loads.

In order to arrive at reasonably rapid methods of stress analysis, it is necessary to make rather sweeping assumptions. It is obvious that the range of applicability of any such method is limited. The present paper concerns itself with beams typical in general form of one class of beams used in airplane construction, that is, with fairly shallow, wide beams, having flat covers, symmetrical about the center line, with two shear webs and with bulkheads that offer no appreciable resistance to deformation out of their planes.

Briefly, the action of such a beam under loads applied at the shear webs is as follows: The transverse shear is taken up by the shear webs. The flanges attached to these shear webs furnish part of the longitudinal stresses required to balance the external bending moment. The strains set up by these stresses induce shear stresses in the skin which, in turn, cause longitudinal stresses in the intermediate stringers attached to the skin until sufficient longitudinal stresses exist at any section to balance the external bending moment.

If the skin between stringers did not deform under the action of the shear stresses, the standard beam formulas would apply. The thin sheet, however, has very little shear stiffness and suffers large deformations under load. As a result, the first intermediate stringer next to a shear web carries a smaller stress than the flange of the shear web, the next intermediate stringer carries less stress than the first one, and so on to the center stringer, which carries the smallest stress. This phenomenon of the interdependence between stringer stresses and shear deformations forms the subject of the present paper.

Apparently Dr. Younger was the first person in this country to give serious attention to this subject. In reference 1 he gives a formula for the efficiency of a box beam with walls of uniform thickness, which may be considered as the limiting case of very many extremely small stringers. Nothing more on the subject was published until two experimental studies appeared in 1936. Reference 2, dealing with the case of a skin-stringer panel in edge compression, includes a theoretical solution for a particular case. Reference 3 deals with a box beam in pure bending, a problem identical with the one treated in reference 2. In both studies the stringer stresses experimentally obtained were used to compute efficiency factors for the shear stiffness of the sheet.

The most important practical problem is the inverse of the problem dealt with in references 2 and 3; namely, given the shear stiffness, to calculate the stringer stresses. The problem is difficult and complex. In order to arrive at any solution, it has been necessary to use a very much simplified concept of the action of the structure, as suggested in references 1 and 2. On the basis of this simplified concept, the analytical solutions for a few very simple cases of axially loaded panels and of beams are derived in this paper. For other cases, it will be shown that a trial-and-error method of solution is feasible.

The analytical solutions as well as the trial-and-error method apply only to very elementary cases, namely, to three-stringer panels under axial load and to beams with a single longitudinal stringer attached at the center line of the cover sheet. It has been considered worth while to devote considerable space to the discussion of these elementary cases for the following reasons:

1. The study of these simple cases greatly facilitates the understanding of the fundamental principles. (It is very strongly urged that anyone desiring to use the
The proposed method of analysis work, by the trial-and-error method, at least one example each of a panel under axial load and of a beam.

2. The simple cases afford a very convenient way of experimentally checking the validity of the assumptions made. Strain-gage tests made for this purpose on a tension panel and on a beam are described in this paper.

3. The solutions obtained for beams with a single longitudinal can be used as checks on the degree of approximation attainable with the "constant-stress method" proposed later for analyzing actual wing beams.

An additional reason for the lengthy discussion will only be mentioned in passing. Under certain conditions, a beam with a single longitudinal stringer may give useful approximations of the stresses in a beam with many stringers. Such a simplified substitute beam makes it possible to obtain some rough ideas on the influence of bulkheads, an influence that was neglected in the present discussion.

Two methods are proposed for winglike structures. One method is the construction of a mechanical analyzer permitting a solution that is "exact" within the assumptions made. The other method is based on the assumption that the structure is so dimensioned as to approach the ideal design of constant flange stress along the span. For this ideal case, the analytical solution can be obtained. The actual case will have deviations from the ideal case, which are termed "faults." These faults are minimized as much as possible by applying corrections, and the stresses caused by the corrections are superposed on the stresses of the ideal case.

**SYMMETRICAL THREE-STRINGER PANEL UNDER AXIAL LOAD**

**FUNDAMENTAL CONSIDERATIONS**

The simplest possible structure in which shear deformation must be taken into account is shown in figure 1 (a). Two stringers, $A$ and $A'$, of equal section, are connected to an intermediate stringer $B$ by means of a thin sheet $C$. The upper edge of this sheet is reinforced by bars $D$. The stringers and the sheet are attached to a foundation $F$.

The important phases of the elastic action of this structure may be visualized with the help of the mechanical model sketched in figure 1 (b). This model represents one-half the structure, which is permissible because the structure is symmetrical. Helical springs represent the stringers $A$ and $B$ and their elastic resistance to longitudinal deformation. Coil springs represent the elastic resistance of the sheet to shear deformation. It is assumed that the stringers carry only longitudinal stresses and that the sheet carries only shear stresses. For the mechanical model it is assumed that guides prevent any deflection of the springs other than that for which they are designed.

The stresses resulting from the load $P$ are shown qualitatively in figure 2. At the top of stringer $A$ the stress is $\sigma_A = P/A_A$, at the top of stringer $B$ it is $\sigma_B = 0$. The shear stresses $\tau$ acting on the sheet gradually take the load out of stringer $A$ and transfer it to stringer $B$. If the panel has sufficient length and if the sheet has sufficient shear stiffness, the stresses $\sigma_A$ and $\sigma_B$ will be very nearly equal at the root.

**EQUATIONS OF THE PROBLEM**

The equations governing the problem under the simplifying assumptions can be very easily set up. Figure 3 shows a strip of length $dx$ cut from the panel and separated into its component parts. The equation of equilibrium gives

$$dF_A = dS_C = -dF_B$$

(See list of symbols, appendix A.)

It should be noted that these equations are written for the structure as shown in figures 1 (b), 2, and 3, which is one-half the original structure in figure 1 (a), so that $A_B$ is one-half the area of stringer $B$ as shown in figure 1 (a). The sign convention used throughout this paper is that tensile forces and stresses are positive and
STRESS ANALYSIS OF BEAMS WITH SHEAR DEFORMATION OF THE FLANGES

that shear forces and stresses in the sheet are positive when caused by positive stresses in the loaded stringer A (or in the flange F in the case of beams).

The elastic deformation of the structure is shown in figure 4. Two corresponding points 1 and 2 are displaced to new positions 1' and 2'. The total displacements are given by

\[ u_A = \int_0^x \frac{\sigma_A}{E} \, dx \quad \text{and} \quad u_B = \int_0^x \frac{\sigma_B}{E} \, dx \]

The shear strain is given by

\[ \gamma = \frac{u_A - u_B}{b} \]

and since

\[ \gamma = \frac{\tau}{G_s} \]

where \( G_s \) is the effective shear modulus, these relations may be combined into

\[ \frac{bE}{G_s} = \int_0^x \sigma_A \, dx - \int_0^x \sigma_B \, dx \]

The last equation may be written

\[ d\tau = \frac{G_s}{E_b} (\sigma_A - \sigma_B) \, dx \] (2)

Equations (1) and (2) may be combined into a differential equation (see appendix B) which, together with the boundary conditions, defines the problem completely. If there are more stringers, a system of simultaneous differential equations results.

SOLUTION OF THE EQUATIONS

For the fundamental case of a symmetrical three-stringer panel of constant cross section, the analytical solutions are given in appendix B for two cases: The panel attached to a rigid foundation and loaded at the free end, and the panel free in space strained by displacing the ends of the stringers a known amount. Combining the two solutions makes it possible to calculate loaded panels attached to an elastically yielding foundation.

For the analysis of three-stringer panels in which the stringer areas and the shear stiffness of the sheet vary along the axis, a trial-and-error method has been found feasible.

The recommended procedure for the trial-and-error method is as follows:

Divide the length \( L \) of the specimen into a suitable number of bays. Tabulate the average values of \( t, A_A, \) and \( A_B \) for each bay.

Assume values for the increment of shear \( \Delta S_c \) in each bay. According to equation (1)

\[ \Delta F_A = -\Delta F_B = \Delta S_c \]

With the assumed values of \( \Delta F_A \) and \( \Delta F_B \) and the known values \( F_A = P \) and \( F_B = 0 \) at the end of the panel, calculate for all stations along the length of the panel the forces in the stringers and then the stresses in the stringers. From these values calculate the shear stresses and the shear forces in the sheet. The method of tabulation is shown in table I. In this example, the values of \( A_A, A_B, \) and \( t \) are constant and need not be tabulated.

The calculated values of \( \Delta S_c \) will not, in general, agree with the originally assumed values. Change the assumed values and repeat the entire process until a satisfactory agreement is reached between the assumed values of \( \Delta S_c \) and the calculated ones.

In the choice of the first set of values for \( \Delta S_c \), the analyst must be guided by previous experience. The only condition known at the outset is

\[ S_c < \frac{P A_B}{A_A + A_B} \]

because this is the maximum possible force that would be transmitted to stringer \( B \) only if the shear deformation were reduced to zero.

The most difficult step, and the one upon which the success of the method hinges, is to compare the calculated \( \Delta S_c \) curve with the assumed one and, on the basis of this comparison, to derive a new curve modified in such a way that the repetition of the entire calculation will yield a calculated \( \Delta S_c \) curve that agrees with the assumed one. No general rule can be given concerning the method beyond stating that decreasing the assumed \( \Delta S_c \) values at any point will raise the calculated ones and vice versa. Some practice is necessary to develop the skill required for this step. Five trials should be sufficient, in general, to obtain an agreement to 1 or 2 percent for five or six bays unless the variations of areas are extreme.

It should be emphasized that the method is a trial-and-error one and not a method of successive approximation, i.e., the calculated \( \Delta S_c \) curve cannot be used as the assumed curve for the next cycle.

EFFECTIVE SHEAR STIFFNESS AND EFFECTIVE STRINGER AREAS

Two quantities must be determined before an analysis can be started—the effective shear stiffnesses and the effective stringer areas.

The shear stiffness of a flat sheet is equal to the shear modulus \( G \) of the material. If the sheet buckles into a diagonal-tension field and the edge members are rigid, the shear stiffness is the theoretical shear stiffness of a diagonal-tension field \( G_s = \frac{G}{4} \) (for duralumin or steel).
The condition of a pure diagonal-tension field is not reached, however, until the buckling shear stress has been considerably exceeded. Consequently, values intermediate between \( G \) and \( \frac{G}{3} \) will occur at stresses not too greatly in excess of the buckling stress (i.e., 3 to 5 times), provided that the edge members are sufficiently stiff. If the edge members are not sufficiently stiff or well braced to take the transverse component of the diagonal tension and particularly if the sheet carries edge compression in addition to shear, the shear stiffness may drop to very low values. Values as low as \( G_i = 0.1G \) have been reported (reference 3); although the numerical accuracy of this particular analysis has been questioned, it serves at least as a useful indication of what may be expected, remembering that this test was stopped long before reaching the ultimate load. Quantitative information on this subject is scarce. Fortunately, as will be shown later, the shear stiffness need not be very accurately known to obtain reasonable accuracy in the stringer stresses.

It is clear that the sheet will not only act as a shear member in accordance with the theory but will also assist in carrying longitudinal stresses. The following assumptions have been used:

1. For a sheet carrying tension in addition to shear, it was assumed that the sheet is fully effective in tension; i.e., the sheet up to a line halfway between the stringers is added to the stringer proper when computing the cross-sectional area of the stringer. This assumption is obviously somewhat unsafe and should be modified when the stringer stresses are high.

2. For a sheet carrying compression in addition to the shear, von Kármán’s formula for effective width was used in the form

\[
2w = 1.9 \sqrt{\frac{E}{\sigma}}
\]

where \( w \) is the effective width (on one side of the stringer) and \( \sigma \) the stress in the stringer. This formula is probably always conservative in the range in question.

**COMPARISON BETWEEN TEST AND CALCULATED RESULTS**

In order to check the validity of the method thus far developed, a test specimen was built to represent a structure corresponding to figure 1 (a). A sketch of the actual test specimen is shown in figure 5. Pin-end steel bars (not shown in the figure) spaced 3 inches apart were used to separate the edge stringers from the central stringer and to take up the transverse component of the diagonal-tension field that developed under load. In each bay between these bars, the strains in the stringers were measured with 2-inch Tuckerman strain gages on both sides of the specimen. This precaution proved necessary because the stresses on the two sides differed so much at some stations that readings on only one side would have been almost useless.

The load was increased from zero to the maximum of 4,800 pounds in five steps. With a very few minor exceptions, the points for any one gage fell on straight lines. For each station, the results obtained on the front and the back of the specimen were averaged and the average values are plotted in figure 6.

---

**Figure 5.** Test panel.

**Figure 6.** Comparisons between calculated and experimental results for tension test panel. (Data from reference 3.)

**Figure 7.** Comparison between calculated and experimental results for compression test panel. (Data from reference 2.)
The calculations were made for the two different assumptions of the shear stiffness indicated on the figure. The second assumption of \( G_s = \frac{1}{4} G \) in the top part was based on the experimentally observed fact that one well-developed diagonal-tension fold showed in the top of the panel on each side, in agreement with the calculation showing that at the maximum load the shear stress in this region was about six times the buckling stress.

The second assumption gives perfect agreement between calculated and test results for the stress in the central stringer. The agreement is not quite so good on the edge stringer, the discrepancy occurring chiefly at the root. Several explanations of the discrepancy may be offered. An error of several percent may be caused by an error in the value of \( E \) assumed to convert strain readings to stress readings. The simple theory used may break down to some extent near the root and, finally, jig deflection may cause errors. The steel triangle used on the lower end is not a rigid foundation, and a slight elastic deformation of this steel triangle under the edge stringers would relieve the edge stringers of some load and throw it into the sheet and possibly into the central stringer. A deformation of about 0.0003 inch would be sufficient to make the calculated stringer stresses equal at the jig end. Undoubtedly the assumptions of effective areas, effective shear stiffness, and jig deflection could be varied within their possible limits to give a much better agreement with the experimental points.

A similar analysis was made for the panel tested in compression as described in reference 2. The results are shown in figure 7. It will be noted that fair agreement with the experimental points is obtained by assuming that the effective shear stiffness is only 0.2 the shear modulus, in marked contrast to the tension panel. The curves calculated with \( G_s = G \) are also given to show the extent to which possible variations in \( G \) affect the stringer stresses.

**BEAMS WITH ONE LONGITUDINAL BEAM OF CONSTANT DEPTH**

The simplest case of a beam subjected to shear deformation of the flange is shown in figure 8. For simplicity of the sketch the flange material on the side not under consideration is assumed to be concentrated at the shear web. This assumption does not influence the analysis when the cover is flat.

For convenience of discussion, the material concentrated at the top of the shear web will be referred to as the "flange" throughout this paper, while the stringer attached to the cover sheet will be referred to as the "longitudinal."

It is again assumed that the longitudinal is cut along the line of symmetry (fig. 8 (b)). The force acting on this halved longitudinal is denoted by \( F_L \); the force on the (tension) flange by \( F_p \). The shear force in the web is denoted by \( S_w \); the shear force in the cover sheet, by \( S_c \).

The governing equations are

\[
\frac{dF_p}{dx} = \frac{dS_w}{h} - dS_c \quad (3a)
\]

\[
-dF_L = dS_c \quad (3b)
\]

\[
dr = -\frac{G_s}{E_h} (\sigma_p - \sigma_l) \, dx \quad (3c)
\]

with the auxiliary equations

\[
\sigma_p = \frac{F_p}{A_p}, \quad \sigma_l = \frac{F_l}{A_l}, \quad S_w = P; \quad dS_c = \tau \, dx
\]

The solution of the resulting differential equation is given in appendix B, Case 3 (a).

**COMPARISON BETWEEN TEST AND CALCULATED RESULTS**

The test panel that had been used in the previously described tension test was slightly modified and attached to two duralumin I-beams to form an open
(a) Closed side.

(b) Open side.

Figure 9.—View of test beam, showing strain gages.
STRESS ANALYSIS OF BEAMS WITH SHEAR DEFORMATION OF THE FLANGES

Figure 10.—Set-up for testing beams.
box beam. Figure 9 shows photographs of the beam with the strain gages in place for a test run; figure 10 shows the test set-up. The cross section of this beam is shown in figure 11.

It should be noted that the cover sheet and the longitudinal were not attached to the bulkheads except at the root. The flange material of the I-beams (including the cover strips riveted to them and the sheet material effective in tension) was replaced, for the purpose of analysis, by equivalent concentrated flanges with a centroidal distance of 2.80 inches (effective depth \( h \) of beam, fig. 8 (a)). The calculated stresses are therefore valid for the flange centroids. For comparison with the measured stresses, the calculated flange stresses were corrected to the outside fiber stresses under the assumption that plane cross sections remain plane for the I-beams with cover strips.

Figure 12 shows the experimental points, the curves calculated for three different assumptions of the shear stiffness, and the stresses calculated by the ordinary bending theory. It can be seen that the experimental points group fairly well about the curve for \( G_s = \frac{G}{4} \), particularly when this curve is corrected for an estimated jig deflection by the formula in appendix B, case 2. Close to the root, however, discrepancies are again observed as in the case of the tension panel. The high flange stress at the station nearest the root may perhaps be explained by nonlinear stress distribution in the I-beams caused by the method of attaching them to the jig, which was not designed for this test. The reduction in shear stiffness of the sheet as compared with the stiffness developed by the same sheet in the tension panel can be ascribed to numerous initial buckles present in the beam but not in the tension panel.

Inspection of figure 12 shows that very large variations of shear stiffness have only a relatively small influence on the bending stresses. This result is due to the fact that, even when the shear stiffness increases to infinity, the bending stresses never exceed a finite limiting value. In many actual structures, the shear stiffness provided is sufficiently large to permit the limiting stress to be approached within a few percent. Practically speaking, this fact means that the shear stiffness need not be very accurately known to obtain the necessary accuracy in the bending stresses.

In a beam with variable depth, the only change in the equations is introduced by the fact that the vertical components of the flange forces balance part of the applied shear, so that the shear in the web now becomes

\[
S_w = S_e - \frac{M}{h} (\tan \beta + \tan \gamma)
\]

where \( \beta \) and \( \gamma \) are the angles of inclination of the tension flange and of the compression flange.

The analytical solution for a special case of a beam with variable depth is given in appendix B as Case 3 (b).

**BEAM OF VARIABLE DEPTH**

**CONSTANT-STRESS SOLUTION FOR BEAMS WITH ONE LONGITUDINAL**

The analytical solutions presented thus far, together with the trial-and-error method, are reasonably adequate for dealing with beams having one longitudinal. There appears to be but slight possibility, however, of extending these solutions to the practical cases of beams with a number of longitudinals. An approximate method will now be developed that can be extended to such beams. The method will first be developed for a beam with a single longitudinal because comparisons can be made with the exact solution to gain some idea of the reliability of the approximate method.
The approximate method is based on the following reasoning. It is the aim of the designer to dimension the structure so that the stress in it is uniform for the given loading. For several reasons this ideal is never reached, but there is usually an effort made to taper the dimensions so as to approach the dimensions of the ideal design. Now the solution for constant stress along the span can be very easily obtained. It is possible, therefore, to consider the actual condition as a superposition upon the ideal case, which can be calculated exactly, of some additional disturbing cases or "faults." These faults can be calculated only approximately, but if they are of minor importance compared with the ideal case, the resulting error of the total solution will be small.

The detailed development of the method is as follows:

The fundamental equation

\[ d\tau = \frac{G_s}{Eb}(\sigma_F - \sigma_L)dx \]  

(6)

can be integrated once, if \( \sigma_F \) and \( \sigma_L \) are constant as assumed, to give

\[ \tau = \frac{\sigma_F - \sigma_L}{Eb} \int_0^x G_s dx = \frac{\sigma_F - \sigma_L}{Eb} \bar{G}_z \]  

(7)

where \( \bar{G}_z \) is the shear stiffness averaged over the distance \( x = 0 \) to \( x = x \), and the \( x \) origin is taken at the root. Integrated again to give the total shear force in the cover sheet

\[ S_C = \int_0^L \tau_s dx = K_1(\sigma_F - \sigma_L) \]  

(8)

For example, if \( G_s \) and \( t \) are constant along the span,

\[ K_1 = \frac{G_s t L}{2Eb} \]

Equation (8) furnishes one relation between \( \sigma_F \) and \( \sigma_L \). One more relation is needed to complete the solution. There are infinitely many conditions from which to choose this relation. At any station along the span, the internal bending moment should equal the external bending moment. The root section has been chosen because in a number of trials it always proved, by far, to be the best choice. Equating the internal and external moment (applied at the root) gives the relation

\[ (\sigma_F A_{F_0} + \sigma_L A_{L_0})h_0 = M_0 \]  

(9)

Now remembering that

\[ S_C = \sigma_L A_{L_0} \]

equations (8) and (9) can be solved for the bending stresses

\[ \sigma_L = \frac{M_0 K_1}{h_0[A_{F_0} A_{L_0} + K_1(A_{F_0} + A_{L_0})]} \]  

(10a)

\[ \sigma_F = \frac{M_0}{h_0[A_{F_0} A_{L_0} + K_1(A_{F_0} + A_{L_0})]} \]  

(10b)

Substituting equations (10a) and (10b) into equation (7) gives

\[ \tau = \frac{x \bar{G}_z M_0}{Eb h_0 [A_{F_0} + K_1(1 + \frac{A_{F_0}}{A_{L_0}})]} \]  

(10c)

Equations (10a), (10b), and (10c) constitute the "pure constant-stress solution" for a beam with a single longitudinal.

The internal bending moment at any station along the span can now be calculated

\[ M_{int} = (\sigma_F A_{F_0} + \sigma_L A_{L_0})h \]

and, in general, this internal moment will not be equal to the applied moment \( M_0 \). This difference constitutes the first fault of the constant-stress solution and will be called the "moment fault."

In order to remove this fault, additional (corrective) bending moments must be added, which are at any station

\[ M' = M_0 - M_{int} \]

the prime denoting corrective moments. The stresses caused by these corrective moments must be computed and added to the stresses of the pure constant-stress solution.

The method of computing the stresses caused by the corrective moments will be approximate and arbitrary as thus far no exact solutions of this problem have been found. The following method was chosen because the underlying assumption is the most obvious one and because the method is very convenient, eliminating the necessity of computing the internal moments, the corrective moments, and the corrective stresses separately.

From equations (10a) and (10b) it follows that the ratio

\[ \left( \frac{\sigma_F}{\sigma_L} \right) = r_0 = \left( 1 + \frac{A_{L_0}}{A_{F_0} A_{L_0}} \right) \]

(11)

The assumption is now made that this ratio remains constant \( (r=r_0) \) along the span and that it holds not only for the stresses caused by the "ideal" moments but also for the stresses caused by the corrective moments. Under this assumption, the direct stresses at any station are given by

\[ \sigma_F = \frac{M_0}{h A_F \left( 1 + \frac{A_{L_0}}{r A_F} \right)} \]

(12a)

\[ \sigma_L = \frac{M_0}{h A_L \left( 1 + \frac{r A_F}{A_L} \right)} \]

(12b)

From these stresses the shear stresses are obtained by using the fundamental relation (2) and integrating from the root toward the tip

\[ \tau = \int_0^x \frac{G_s}{Eb}(\sigma_F - \sigma_L)dx \]

(12c)

The moment fault has now been removed; that is, the internal moments equal the applied moments when the stresses as given by equations (12a) and (12b) exist in
the flange and in the longitudinal. But equation (12c) follows directly from equations (12a) and (12b) and the stresses given by (12a) and (12c) will not, in general, fulfill the fundamental equation (3a) of equilibrium of the flange element. Equation (3a) requires that, for equilibrium of the flange element, the increment of shear force in the cover should be

$$\Delta S_{cs} = \frac{S_e}{h} \Delta x - \Delta F_p$$

where the additional subscript S denotes the increment required for static equilibrium. The increment of shear force actually developed is

$$\Delta S_{ce} = \tau \Delta x$$

where the subscript E refers to the fact that this increment is provided by the elastic deformations of the flange and the longitudinal. Failure of the shear-force increments given by equations (13) and (14) to be identical constitutes the second fault of the constant-stress solution, the so-called “shear fault.”

Static equilibrium for the flange elements would be restored if corrective shear-force increments were introduced equal to the differences of these two sets of shear-force increments

$$\Delta S_{c}' = \Delta S_{cs} - \Delta S_{ce}$$

where the prime again denotes a correction. The corrective shear force $S_{c}'$ at any station is obtained by integrating from the tip to the desired station, the force being zero at the tip. The corrections to be added to the stresses would then be given by

$$\sigma_p' = \frac{S_p'}{A_p}, \quad \sigma_L' = -\frac{S_L'}{A_L}, \quad \tau' = \frac{\Delta S_c'}{\Delta x}$$

(Care must be taken in determining the signs of the corrective stresses. The safest method is to compare their direction with the direction of the stresses given by the pure constant-stress solution.)

Introducing these corrective stresses would restore static equilibrium but would again upset the basic elastic relation given by equation (6). A compromise must therefore be made by using only a fraction $C_1$ of the correction

$$\sigma_p' = C_1 \frac{S_p'}{A_p}, \quad \sigma_L' = -C_1 \frac{S_L'}{A_L}, \quad \tau' = C_1 \frac{\Delta S_c'}{\Delta x}$$

These stress corrections are added to the stresses obtained from equations (12a), (12b), and (12c) to obtain the final corrected stresses $\sigma_{pcorr}$, $\sigma_{Lcorr}$, and $\tau_{corr}$.

Values of $C_1$ may be established by comparing a number of exact solutions with the corresponding constant-stress solutions; an averaged curve is shown in figure 13.

In order to gain some idea of the range of applicability of the constant-stress solution, a series of related beams was calculated. The characteristics of three of these beams are given in table II. The first set of calculations was made by using the analytical solutions given in appendix B for beam $A$ and by using the trial-and-error method for beams $B$ and $C$. The second set of calculations was made by using the constant-stress solution as described. The results of the calculations are shown in figures 14 to 16.

For beam $B$, the stresses given by the pure constant-stress solution are also shown. Beam $B$ is a constant-stress beam when analyzed by the ordinary bending theory and has zero moment fault. The complete analysis for this beam is given as an example in appendix C.

It is to be expected that, in general, there will be smaller differences between the constant-stress solution and the exact solution for beams with small moment fault than for beams with large moment fault. This expectation is borne out by the results. Beam $B$,

![Figure 13](image13)

**Figure 13.** Correction factor, $C_1$.

![Figure 14](image14)

**Figure 14.** Stresses in beam $A$. 

the span is concerned, shows also good agreement for the bending stresses. The agreement is not quite so good for the shear stresses.

Considering all the factors involved, it seems safe to assume that the constant-stress solution will give satisfactory results in practical cases for the maximum stresses, provided that the correction introduced by the shear fault is not larger than about 20 percent of the stress given by the pure constant-stress solution.

BEAMS WITH MANY LONGITUDINALS

YOUNGER'S SOLUTION

Actual wing structures are built as box beams with many longitudinals, and the depth of the beam as well as all cross-sectional areas varies along the span.

The first attempt at obtaining a solution for a multi-stringer beam was made by Younger (reference 4). He considered the limiting case of infinitely many longitudinals (i.e., a plate cover as shown in fig. 17) and assumed the box to be of constant section; for the distribution of the bending moments he assumed a cosine law.

Younger's solution and its extension to arbitrary moment curves are given in appendix B. It should be noted that this solution does not fulfill the equation of equilibrium for the flange element (the differential equation does not hold along the flange) so that a shear-fault correction is necessary, as discussed in connection with the constant-stress solution for the beam with a single longitudinal.

span that a more general method appeared desirable. The constant-stress solution was developed to fill this need of practical stress analysis.

The principles of the constant-stress solution have been discussed in detail for beams with a single longitudinal. The extension of the solution to beams with many longitudinals is given in appendix B. The practical procedure of applying it is essentially identical with the procedure outlined for beams with a single longitudinal. The constant $K_3$ is computed and used to compute the constant $K_5$ for the root section, using equation (B–27). The stresses at a number of stations along the span are then obtained by the formula

$$
\sigma = \frac{M \cosh K_5 y}{h \left( A_f \cosh K_5 b + \frac{A_L}{K_5 b} \sinh K_5 b \right)}
$$

(17)

where $y$ varies from $y=0$ for the center line of the beam to $y=b$ for the flange. The shear stress in the cover sheet next to the flange is obtained by integrating from the root outward the expression

$$
\left( \frac{dz}{dx} \right)_r = \frac{G_t}{E} \sigma_y K_5 \tanh K_5 b
$$

(18)

where $\sigma_y$ is obtained from equation (17) by setting $y=b$. Equation (18) is obtained from equations (B–20) and (B–25).
The increments of corrective shear force are obtained by using equations (13), (14), and (15). After the integration of (15) in from the tip to obtain the corrective shear force $S_c'$, the correction to the flange stress is calculated by the first expression of (16); the correction to the shear stress is calculated by the last expression of (16).

The calculation of the correction to the stress $\sigma_L$ is somewhat more complicated because it varies along the chord. The total force on all longitudinals, using equation (17), is given by

$$F_L = \int_0^b \sigma_L \frac{A_L}{K_L} dy = \frac{A_L}{K_L} \sigma_{CL} \sinh K_L b$$

where $\sigma_{CL}$ denotes the stress at the center line of the beam obtained from equation (17) by setting $y=0$. In accordance with (16), only a part of the corrective shear force is applied so that the corrected total force on the longitudinals is

$$F_{L corr} = F_L - C_l S_c'$$

Assume now that the corrected stresses in the longitudinals are distributed chordwise according to the law

$$\sigma_{corr} = \sigma_{CL corr} \cosh Y b$$

The unknown $Y$ can be found from the equation

$$\tanh \frac{Y b}{Y b} = \frac{F_{L corr}}{A_L \sigma_{F corr}}$$

which is based on the premise that

$$\sigma_{F corr} = \sigma_{F corr}$$

for $y=b$. After $Y$ has been found, the corrected stress at the center line is found from

$$\sigma_{CL corr} = \sigma_{F corr} \sech Y b$$

and equation (21) can then be used to calculate the stresses at intermediate values of $y$. The right-hand side of equation (22) is the ratio of the average stress in the longitudinals to the stress in the flange. In general, this ratio will be less than unity; however, figure 16 shows that for a beam with a single longitudinal the stress in the longitudinal may be larger than the stress in the flange over a part of the span, and similarly the right-hand side of equation (22) sometimes may exceed unity. In such a case, equations (21) and (22) may be replaced by

$$\sigma_{corr} = \sigma_{CL corr} (2 - \cosh Y y)$$

and equation (21a) can then be used to calculate the stresses at intermediate values of $y$.

The solution of equations (22) and (22a) can be effected by inspection of tables. For practical purposes it should be sufficient to use the curve given on figure 18.

As examples, beams $A$ and $B$ were analyzed under the assumption that longitudinals with the total cross-sectional area $A_L$ are distributed uniformly along the chord. The results are shown in figures 19 and 20. It will be seen that the stress at the center line of the beam is very low. If all longitudinals are of the same cross section, they must be designed to the stress in the first longitudinal adjacent to the flange. Consequently,
assumption of $A_L$ being uniformly distributed may be fulfilled, for instance, by using longitudinals of large cross-sectional area but widely spaced near the flange and longitudinals of small cross-sectional area but closely spaced near the center line. Although such an arrangement would not increase the over-all structural efficiency, it might under certain conditions offer manufacturing advantages.

**MECHANICAL ANALYZER**

The constant-stress solution is always approximate. When the moment and shear corrections are large, doubts may arise as to whether the solution is sufficiently accurate. It might be advantageous to construct a mechanical analyzer to deal with such cases. One possibility for such an analyzer would be actually to build units representing the mechanical model sketched in figure 1 (b). The springs might be cantilever springs, so that their stiffnesses could be varied by changing their lengths. Each unit would represent one bay of the trial-and-error method of solution and would have one spring to represent the stringer stiffness and one spring to represent the shear stiffness of the sheet attached to one side of the stiffener.

The chief difficulty in the design of such an analyzer would probably be in reducing the friction between the units and the guides necessary to align them. A fairly large number of units would be necessary to represent a wing cover, which would mean a fairly expensive instrument. This disadvantage is counterbalanced by the possibility that the instrument would offer in a comparatively short time quite an exact analysis, including the effects of bulkheads and of yielding supports. The main errors in this solution would be those caused by the finite length of bays.

**CONCLUSION**

The art of stress-analyzing shell structures is of recent origin, and any methods of analysis proposed must go through a process of trial and development. Development of the method of shear-deformation analysis is desirable in several directions; e.g., exact solutions should be found to replace the constant-stress solution and methods should be devised to calculate the influence of bulkheads.

Rough approximate calculations on bulkhead effect can be made by assuming that all the longitudinals are relocated at the center line of the beam. For beams with a single longitudinal, the effect of bulkheads can be calculated. A series of systematic comparisons between the extended solution of Younger and Case 3 (a) of appendix B indicates that for a certain range the single-longitudinal assumption may yield acceptable approximations when used in conjunction with suitable correction factors. The comparisons are not given, however, because they might be misleading in view of the shear fault of Younger's solution. Calculations made thus far indicate that in practical cases the effect of the bulkheads is very small.

It should be emphasized that analyzing shell structures is an art rather than a science. The arithmetic of analyzing highly redundant structures can be reduced to manageable proportions only by making assumptions that will be valid only within a certain range. This fact leads to the unfortunate, but inevitable, conclusion that the analysis of such structures cannot be made entirely by handbook and formula but must be guided by engineering judgment.

**Figure 20.** Stresses in beam $B$ with $A_L$ uniformly distributed along chord.

Langley Memorial Aeronautical Laboratory, National Advisory Committee for Aeronautics, Langley Field, Va., June 3, 1937.
APPENDIX A

Subscripts have the following significance:

A, loaded stringer $A$ shown in figures 1, 2, 21, and 22.
B, unloaded stringer $B$ shown in figures 1, 2, 21, and 22.
C, cover sheet.
$F$, flange of beam.
$L$, longitudinal of beam.
$W$, shear web.
a, applied shears and bending moments.
e, effective.
0, root section.
c, compression.
t, tension.
int, internal.
corr, corrected.
$S$, static equilibrium.
$E$, elastic equilibrium.
$CL$, center line.
APPENDIX B

SOLUTIONS OF DIFFERENTIAL EQUATIONS FOR SYMMETRICAL STRUCTURES OF CONSTANT CROSS SECTION

SIGN CONVENTIONS

Forces and stresses in stringers are positive when tensile. Shear forces and stresses in the sheet are positive when caused by positive stresses and strains in the loaded stringer A in the case of axially loaded panels or in the flange F in the case of beams.

CASE 1—THREE-STRINGER PANEL ON RIGID FOUNDATION WITH AXIAL LOAD

The two possible cases shown in figures 21(a) and 21(b) can be mathematically treated by taking one-half the panel, as shown in figure 21(c), which also

gives the notation to be used. The derivation of the fundamental equations is given in the main body of this paper. Slightly modified for the purpose of deriving the basic differential equation, these equations are

\[ \sigma_A' = \frac{\tau t}{A_A} \quad \text{and} \quad \sigma_B' = -\frac{\tau t}{A_B} \]  

(B-1)

\[ \tau' = \frac{G_s}{E_b} (\sigma_A - \sigma_B) \]  

(B-2)

where the primes denote differentiation with respect to \( x \).

Differentiating equation (B-2) again and substituting into the result from equation (B-1),

\[ \tau'' - \frac{G_s t}{E_b} \left( \frac{1}{A_A} + \frac{1}{A_B} \right) = 0 \]  

(B-3)

The boundary conditions are

at \( x = 0 \), \( \tau = 0 \)

and

at \( x = L \), \( \sigma_A = \frac{P}{A_A} \) and \( \sigma_B = 0 \)

The result is

\[ \tau = \frac{P G_s}{A_A E_b K \cosh KL} \sinh Kx \]  

\[ \sigma_A = \frac{P}{A_A + A_B} \left( \frac{1}{A_A} \cosh Kx \right) \]  

(B-4)

\[ \sigma_B = \frac{P}{A_B} \left( \frac{1}{A_B} \cosh Kx \right) \]

where

\[ K^2 = \frac{G_s t}{E_b} \left( \frac{1}{A_A} + \frac{1}{A_B} \right) \]  

(B-5)

In reference 2 the formula

\[ f_s = \frac{2P}{A_t} \cosh px - \tanh px \tan \left( \frac{pL \sinh px}{4} \right) \]  

(B-6)

is given for the special case where the area of the edge stiffener is twice the area of the central stiffener. Taking account of the differences in notation and coordinate systems used, this result agrees with the general formula given under (B-5).

It should be noted that the final formulas (B-5) become invalid when either \( t \) or \( G_s \) approaches zero because in these cases the equation (B-3) becomes invalid. The solution for such cases is obtained by using the fundamental equations (B-1) and (B-2) directly.

An analogous procedure must be used for Cases 2 and 3.

CASE 2—THREE-STRINGER PANEL STRAINED BY MOTION OF SUPPORTS

The differential equation for the case of figure 22 is

\[ \tau = \frac{G_s t}{E_b} \cosh Kx \]  

\[ \sigma_A = -\frac{t}{K A_A} \sinh Kx \]  

\[ \sigma_B = -\frac{t}{K A_B} \sinh Kx \]  

(B-7)

The result is

\[ \tau = \frac{t}{K} \cosh KL \]  

\[ \sigma_A = -\frac{t}{K A_A} \sinh KL \]  

\[ \sigma_B = -\frac{t}{K A_B} \sinh KL \]  

(B-8)

where \( K \) has the same meaning as in (B-6).
CASE 3—CANTILEVER BEAM WITH ONE STRINGER

(a) Uniform depth, concentrated load at tip.
(b) Depth decreasing linearly to zero, uniformly distributed load.

Figure 8 shows the notation used for both cases. (Note that the x origin is at the tip.) The fundamental equations are for Case 3 (a)

\[
\begin{align*}
\sigma_p A_p &= \frac{P}{h} - z
\\
\sigma_L A_L &= z
\\
\tau' &= -\frac{G_s}{E_b} (\sigma_p - \sigma_L)
\end{align*}
\]

which gives the differential equation

\[
\tau'' - \frac{G_s}{E_b} \left( \frac{1}{A_p} \frac{\partial^2}{\partial x^2} + \frac{1}{A_L} \frac{\partial^2}{\partial x^2} \right) + \frac{PG_L}{A_p E_b h} = 0
\]

The boundary conditions are

\[
\begin{align*}
&x=0, \quad \sigma_p=0, \quad \sigma_L=0 \\
&x=L, \quad \tau=0
\end{align*}
\]

The result is

\[
\begin{align*}
\tau &= \frac{P}{th(1+\frac{A_p}{A_L})} \left( 1 - \cosh Kx \right) \\
\sigma_p &= \frac{P}{h(A_L + A_p)} \left( x - \frac{\sinh Kx}{K \cosh KL} \right) \\
\sigma_L &= -\frac{1}{A_p} \left( \frac{M}{h_x} - \sigma_L A_L \right)
\end{align*}
\]

where \( K \) has again the same meaning as in (B-6) with \( A_p \) and \( A_L \) substituted for \( A_A \) and \( A_p \).

In Case 3 (b), \( wL^2/2 \) is substituted for \( P; \) \( h \) in this case is the depth at the root.

![Figure 23.—Cantilever beam with concentrated load not at tip.](image)

The case of a beam loaded by a concentrated load not at the tip is a simple problem in indeterminate structures. The beam is cut just outboard of the load (fig. 23) and the stresses in the cantilever part are calculated (Case 3 (a)). From these stresses, the distortion of the beam section at the cut; i.e., the relative displacement of the tips of the flange \( F \) and the longitudinal \( L \), can be calculated. A system of forces \( X \) is then applied to equalize the distortion of the cantilever tip and of the inboard end of the “overhang,” utilizing the formulas of Case 2.

CASE 4—CANTILEVER BEAM WITH ORTHOTROPIC COVER PLATE

Younger's solution for a beam of constant section.— The beam and the coordinate system used are shown in figure 17. It should be noted that the \( x \) direction is opposite to that used in Cases 3 and 4.

Under the assumptions that the transverse stresses and strains are negligible (Poisson’s ratio equal to zero), and that \( G_s \) is independent of \( E \), the differential equation of the cover is

\[
\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0
\]

where \( u \) is the displacement of any point on the cover in the \( x \) direction.

The boundary conditions are

\[
\begin{align*}
&x=0, \quad u=0 \quad \text{and} \quad \partial u/\partial y=0 \\
&x=L, \quad \partial u/\partial x=0 \\
&y=0, \quad \partial u/\partial y=0
\end{align*}
\]

This equation was established by Younger (reference 4, pp. 36-47). For the solution he assumed that the external bending moment (on the whole beam) is given by

\[
M = M_0 \cos \frac{\pi x}{2L}
\]

and obtained for the longitudinal stress in the cover

\[
\sigma = \frac{M_0 \cosh \frac{x}{b} \cos \frac{\pi x}{2L}}{2h \left( A_p \cosh \frac{x}{b} + A_L \frac{2KL}{\pi} \sinh \frac{\pi b}{2KL} \right)}
\]

and for the shear stress

\[
\tau = \frac{M_0 G_s \sinh \frac{\pi y}{2KL} \sin \frac{\pi x}{2L}}{2KA_p \cosh \frac{\pi b}{2KL} + 4K^2L \sinh \frac{\pi b}{2KL}}
\]

where \( K \) is defined by

\[
K^2 = \frac{G_s}{E}
\]

Extension of Younger’s solution.— Younger’s solution can be somewhat extended. The external bending moment can be represented by a superposition of several terms:

\[
M = M_1 \cos \frac{\pi x}{2L} + M_2 \cos \frac{3\pi x}{2L} + M_3 \cos \frac{5\pi x}{2L}
\]

where the \( m \)’s are odd integers.
The values $M_1 \ldots M_m$ are chosen so that the sum of the terms equals the given external bending moment at $m$ points other than the tip, where it is assumed that $M=0$. In order to make comparisons with Case 3, the bending moment caused by a tip load was expressed by

$$M = PL \left( 0.821 \cos \frac{\pi x}{2L} + 0.101 \cos \frac{3\pi x}{2L} + 0.045 \cos \frac{5\pi x}{2L} + 0.033 \cos \frac{7\pi x}{2L} \right)$$  \hspace{1cm} (B-19)

The stresses corresponding to the $m$th term are given by

$$\sigma_m = \frac{M_m \cosh \frac{m\pi y}{2KL} \cos \frac{m\pi x}{2L}}{2b} \left( A_r \cosh \frac{m\pi b}{2KL} + \frac{A_L}{b} \frac{2KL}{m\pi} \sinh \frac{m\pi b}{2KL} \right)$$

$$\tau_m = \frac{M_m G_r}{2KL} \left( \sin \frac{m\pi y}{2KL} \sin \frac{m\pi x}{2L} \right) \left( 2KA_r \cosh \frac{m\pi b}{2KL} + \frac{A_LAK^2L}{b} \frac{2KL}{m\pi} \sinh \frac{m\pi b}{2KL} \right)$$

The assumptions of Poisson’s ratio being zero and $G$ being independent of $E$ are, strictly speaking, incompatible. The physical picture conforming to these assumptions is not a plate but a system of stringers carrying only longitudinal stresses tied together by a sheet carrying only shear stresses. This picture is realized very nearly in practice by a skin-stringer cover, the only difference being that the total cross-sectional area of the stringers is not necessarily equal to the area of the sheet, as in the case of the plain cover sheet. All the equations written for the plain cover sheet apply, therefore, to the skin-stringer cover if only (B-17) is replaced by

$$K^2 = R \frac{G_r}{E}$$ \hspace{1cm} (B-17a)

where $R$ is the ratio of sheet area to area of longitudinal.

**Constant-stress solution.**—The coordinate system is that shown in figure 17. Under the assumption that $\sigma =$ constant for each longitudinal, the fundamental relation

$$\frac{d\tau}{dx} = \frac{G_r \Delta \sigma}{E\Delta y}$$ \hspace{1cm} (B-20)

can be integrated once to give

$$\tau = \frac{\Delta \sigma}{E\Delta y} \int_0^x G_r dx = \frac{x \Delta \sigma}{E\Delta y} G_r$$ \hspace{1cm} (B-21)

where $G_r$ is the shear stiffness averaged over the distance $x=0$ to $x=x$. Integrating again

$$S_c = \int_0^L \tau_x dx = \int_0^L \frac{\Delta \sigma}{E\Delta y} G_r dx$$

In any given case this integration can be performed and the result is

$$S_c = K_2 \Delta \sigma \frac{\Delta y}{dy}$$ \hspace{1cm} (B-22)

where

$$K_2 = \int_0^x E \tau_x dx$$

Now

$$S_c = \int_0^y \sigma \Delta y$$

(see fig. 24) or

$$\int_0^y \sigma \Delta y = \sigma \int_0^y \Delta y$$ \hspace{1cm} (B-23)

**Differentiating (B-22) and equating to (B-23)**

$$\frac{d\sigma}{dy} = -\frac{A_L}{bK_2}$$ \hspace{1cm} (B-24)

assuming that $K_2$ is independent of $y$.

The boundary conditions are

1. at $y=0$, $\tau = 0$ for any $x$. Therefore $\frac{d\sigma}{dy} = 0$
2. at any desired reference station $R$, the internal moment equals the external moment $M_R$.

The solution is

$$\sigma = \frac{M_R \cosh K_3 y}{h_b\left( A_r \cosh K_3 b + \frac{A_L}{b} \sinh K_3 b \right)}$$ \hspace{1cm} (B-25)

$$\tau = \frac{\sigma}{E} K_3 x \tanh K_3 y$$ \hspace{1cm} (B-26)

where $K_3$ is defined by

$$K_3 = \frac{A_L}{bK_2} - \frac{A_L}{b} \int_0^x \frac{\tau_x dx}{E}$$ \hspace{1cm} (B-27)

It may be noted that if $G_r$ and $t$ are not varied along the span, the constant $K_3$ is identical with the corresponding constant of Younger’s solution except for a 10 percent difference in the numerical factor, namely, $\sqrt{2}$ against $\pi/2$. 

**Figure 24.—Free-body diagram of cover plate.**
APPENDIX C

ANALYSIS OF BEAM B

The dimensions and the loading of the beam are shown in table II.

ORDINARY BENDING THEORY

\[
\sigma = \sigma_L = \sigma = \frac{M}{h(A_p + A_L)} = \frac{2,800,000}{24(1.875 + 1.875)} = 31,100 \text{ lb. per sq. in.}
\]

CONSTANT-STRESS SOLUTION

Since \( G_c \) is assumed constant along the span, \( G_c = G_e \) and, from equation (7),

\[
\tau = (\sigma_p - \sigma_L) \frac{G_c}{E_b}
\]

From equation (8)

\[
S_c = \int_0^L (\sigma_p - \sigma_L) \frac{G_c}{E_b} \left( 1 - \frac{x}{L} \right) dx
= (\sigma_p - \sigma_L) \frac{G_c}{E_b} \int_0^L x \left( 1 - \frac{x}{L} \right) dx
= (\sigma_p - \sigma_L) \frac{0.2 \times 0.040}{24} \int_0^{380} x \left( 1 - \frac{x}{280} \right) dx
= 0.35(\sigma_p - \sigma_L)
K_1 = 4.35
\]

From equation (10a)

\[
\sigma_L = \frac{2,800,000 \times 4.35}{24(1.875 + 1.875 + 4.35(1.875 + 1.875))}
= 25,550 \text{ lb. per sq. in.}
\]

From equation (10b)

\[
\sigma_p = \frac{2,800,000(1.875 + 4.35)}{24(1.875 + 1.875 + 4.35(1.875 + 1.875))}
= 36,500 \text{ lb. per sq. in.}
\]

Substituting in equation (7) for the shear stress at the tip

\[
\tau_{max} = \frac{(36,500 - 25,550) \times 280 \times 0.2}{24} = 25,560 \text{ lb. per sq. in.}
\]

The calculation of the shear correction is shown in table III.

TRIAL-AND-ERROR SOLUTION

Take \( \Delta x = 40 \text{ in.} \)

\[
S_w \Delta x = \frac{wxL \Delta x}{2h_0} = \frac{6wL}{2h_0} \Delta x = \frac{71.4 \times 280 \times 40}{2 \times 24} = 16,670 \text{ lb.}
\]

\[
\Delta F_p = 16,670 - \Delta S_c
\]

\[
\Delta \tau = \frac{G_c \Delta x}{E_b} (\sigma_p - \sigma_L) = \frac{0.2 \times 40}{24} (\sigma_p - \sigma_L) = 0.333(\sigma_p - \sigma_L)
\]

A typical cycle of the calculation is shown in table IV.

Absolute coefficients of moment:

\[ C_L = \frac{L}{q_b S} \]  
\[ C_m = \frac{M}{q_b S} \]  
\[ C_n = \frac{N}{q_b S} \]

Angle of set of control surface (relative to neutral position), \( \delta \). (Indicate surface by proper subscript.)

4. PROPELLER SYMBOLS

- \( D \): Diameter
- \( p \): Geometric pitch
- \( p/D \): Pitch ratio
- \( V' \): Inflow velocity
- \( V_n \): Slipstream velocity
- \( T \): Thrust, absolute coefficient \( C_T = \frac{T}{\rho n^2 D^4} \)
- \( Q \): Torque, absolute coefficient \( C_Q = \frac{Q}{\rho n^2 D^5} \)
- \( P \): Power, absolute coefficient \( C_P = \frac{P}{\rho n^5 D^5} \)
- \( C_s \): Speed-power coefficient \( = \frac{s}{\rho V'^2} \)
- \( \eta \): Efficiency
- \( n \): Revolutions per second, r.p.s.
- \( \Phi \): Effective helix angle \( = \tan^{-1} \left( \frac{V}{2\pi n} \right) \)

5. NUMERICAL RELATIONS

- 1 hp. = 76.04 kg-m/s = 550 ft-lb./sec.
- 1 metric horsepower = 1.0132 hp.
