### 2. GENERAL SYMBOLS

- **W**<sub>r</sub>, Weight = *mg*
- **g**<sub>r</sub>, Standard acceleration of gravity = 9.80665 m/s<sup>2</sup> or 32.1740 ft./sec.<sup>2</sup>
- **m**<sub>r</sub>, Mass = *W* / *g*
- **I**<sub>r</sub>, Moment of inertia = *mk*<sup>2</sup>. (Indicate axis of radius of gyration *k* by proper subscript.)
- **µ**<sub>r</sub>, Coefficient of viscosity

### 3. AERODYNAMIC SYMBOLS

- **S**<sub>L</sub>, Area
- **S**<sub>α</sub>, Area of wing
- **G**<sub>r</sub>, Gap
- **b**<sub>r</sub>, Span
- **c**<sub>r</sub>, Chord
- **b**<sup>2</sup><sub>r</sub>, Aspect ratio
- **S**<sub>r</sub>, True air speed
- **q**<sub>r</sub>, Dynamic pressure = \( \frac{1}{2} \rho V^2 \)
- **L**<sub>r</sub>, Lift, absolute coefficient \( C_L = \frac{L}{qS} \)
- **D**<sub>r</sub>, Drag, absolute coefficient \( C_D = \frac{D}{qS} \)
- **D**<sub>0</sub>, Profile drag, absolute coefficient \( C_{D_0} = \frac{D_0}{qS} \)
- **D**<sub>0</sub>, Induced drag, absolute coefficient \( C_{D_1} = \frac{D_1}{qS} \)
- **D**<sub>p</sub>, Parasite drag, absolute coefficient \( C_{D_p} = \frac{D_p}{qS} \)
- **C**<sub>r</sub>, Cross-wind force, absolute coefficient \( C_r = \frac{C}{qS} \)
- **R**<sub>r</sub>, Resultant force

- **i**<sub>α</sub>, Angle of setting of wings (relative to thrust line)
- **i**<sub>1</sub>, Angle of stabilizer setting (relative to thrust line)
- **Q**<sub>r</sub>, Resultant moment
- **Ω**<sub>r</sub>, Resultant angular velocity

- **VI**<sub>r</sub>, Reynolds Number, where *l* is a linear dimension (e.g., for a model airfoil 3 in. chord, 100 m.p.h. normal pressure at 15° C., the corresponding number is 234,000; or for a model of 10 cm chord, 40 m.p.s., the corresponding number is 274,000)

- **C**<sub>p</sub>, Center-of-pressure coefficient (ratio of distance of c.p. from leading edge to chord length)
- **α**<sub>r</sub>, Angle of attack
- **ε**<sub>r</sub>, Angle of downwash
- **α**<sub>α</sub>, Angle of attack, infinite aspect ratio
- **α**<sub>i</sub>, Angle of attack, induced
- **α**<sub>a</sub>, Angle of attack, absolute (measured from zero-lift position)
- **γ**<sub>r</sub>, Flight-path angle

REPORT No. 660

EXPERIMENTAL INVESTIGATION OF THE MOMENTUM METHOD FOR DETERMINING PROFILE DRAG

By Harry J. Goett

SUMMARY

An experimental investigation has been conducted in the full-scale tunnel to determine the accuracy of the Jones and the Betz equations for computing profile drag from total- and static-pressure surveys in the wake of wings. Surveys were made behind 6- by 36-foot airfoils of the N. A. C. A. 0009, 0012, and 0018 sections at zero lift and behind the N. A. C. A. 0012 airfoil at positive lifts. The surveys were made at various spanwise positions and at distances behind the airfoil ranging from 0.05c to 3.00c.

The reduction of the test data by either the Jones or the Betz equation gave profile-drag coefficients agreeing within 2 percent with those obtained by force tests at zero lift. The variation of the profile drag determined at stations from 0.05c to 3.00c behind the trailing edge was small and the error resulting from the induced field of a lifting airfoil did not exceed 2.5 percent at a C_L of 1.0 and a spanwise station of 0.78 b/2.

INTRODUCTION

The use of the momentum method for the determination of profile drag has recently increased, owing mainly to the equations developed by Betz (reference 1) and by Jones (reference 2) by which the method has been made applicable in the region of increased static pressure close behind a body. The derivation of these equations, which are based on the original principle stated by Froude in 1874, requires certain assumptions. The errors introduced by these assumptions have been the subject of theoretical analyses (references 2 and 3), which have set an upper limit for the errors involved but fail to define their actual value.

The investigation reported herein was conducted to determine experimentally the magnitude of these errors by determining the effect of a number of variables upon the measured drag. (See reference 4.) The necessary wake surveys were made in the N. A. C. A. full-scale wind tunnel behind symmetrical airfoils of three thickness ratios. The effect of distance behind the airfoils was first investigated by a comparison of drag determinations made at locations ranging from 0.05c to 3.00c behind the trailing edge. A check was then obtained on the accuracy of the method by a comparison with force-test drag measurements at zero lift. Finally, the effect of the induced-flow system of a lifting wing was investigated.

SYMBOLS

The symbols used in the report are defined as follows:

- H_0, free-stream total pressure.
- H_1, H_2, H_3, total pressures in field of airfoil.
- P_0, free-stream static pressure.
- P_1, P_2, P_3, static pressures in field of airfoil.
- q_0, free-stream dynamic pressure, 1/2ρU_0^2.
- U_0, free-stream velocity.
- U_1, U_2, U_3, local velocity in field of airfoil.
- U_{0*}, hypothetical velocity in wake (Betz equation).
- y, vertical coordinate of point.
- c, airfoil chord.
- dS, dS_1, dS_2, dS_3, elemental areas.
- ρ, density.
- b, airfoil span.
- v, velocity along the Y axis.
- w, velocity along the Z axis.
- D_0, airfoil profile drag.
- C_{D_s}, airfoil profile-drag coefficient.
- C_{L,0}, section profile-drag coefficient.
- C_L, airfoil lift coefficient.
- c_l, section lift coefficient.

EXPERIMENTAL INVESTIGATION

APPARATUS

The experimental work was conducted in the N. A. C. A. full-scale wind tunnel (reference 5). This tunnel has a turbulence factor of 1.1 as determined by sphere tests (reference 6). A typical static-pressure gradient along the axis of the tunnel (jet empty) is shown in figure 1. This gradient was allowed for in determining the free-stream reference pressure for the momentum measurements. The buoyancy effect of the gradient is small.

Three 6- by 36-foot rectangular airfoils having N. A. C. A. 0009, 0012, and 0018 sections were used in these tests. The airfoils, which were covered with
\[ D_0 = \rho W^2 \int U_3(U_0 - U_3) dS \] (1)

where \( W \) indicates the integration is confined to the wake region. For practical reasons, it is desirable
in most cases to make the survey in the region close behind the airfoil where \( p \) is in excess of \( p_o \) (fig. 4 (b)). In this region the drag will be equal to

\[
D_o = \int \int (p_1 + \rho U_1^2) dS_1 - \int \int (p_2 + \rho U_2^2) dS_2
\]

where both integrations are carried to infinity.

Since it is impossible to survey to infinity as required by equation (2), this equation must be transformed into one involving only quantities in the wake region. This transformation has been made by Betz (reference 1) and by Jones (reference 2).

Betz builds up a hypothetical flow by means of a system of sources of such strength that the total pressure in the wake of the body is restored to the value it would have in potential flow. (See fig. 4, \( H_o = H_o, \ U_2 = U_2' \)). This system has a resultant thrust equal to the thrust of the sources. It differs from the real system only in the region of the wake so that the difference in thrust between the two systems is equal to the difference in momentum per unit time passing through the wake region of each. It then follows that

\[
\text{Drag of real system} = \text{Difference in thrust between hypothetical and real systems} - \text{Thrust of hypothetical system}
\]

Thus, the integration over the region external to the wake is eliminated and the expression for profile drag reduces to

\[
D_o = \int \int (H_o - H_2) dS + \frac{\rho}{2} \int \int (U_2' - U_2)(U_2' + U_2 - 2U_0) dS
\]

In terms of total and static pressures to be measured, the section profile-drag coefficient becomes

\[
c_{d_0} = \frac{1}{c} \int \int \frac{(H_o - H_2)}{H_o - p_o} \left[ \frac{\sqrt{H_o - p_2} - \sqrt{H_o - p_2}}{\sqrt{H_o - p_2} + \sqrt{H_o - p_2}} \right] dS
\]

The last step involves the assumption that, for a lifting airfoil,

\[
H_2 = \frac{1}{2} \rho U_2^2 + p_2
\]

instead of

\[
H_2 = \frac{1}{2} \rho (U_2^2 + v_2^2 + w_2^2) + p_2
\]

Jones (reference 2) assumes a hypothetical flow in the wake in which there is no energy interchange between tubes of flow in the wake behind the point of measurement and consequently that Bernoulli’s equation may be applied to these tubes of flow. On the basis of such an assumption, the total and the static pressures measured close behind a body in a region of increased static pressure give sufficient data to obtain the corresponding velocity loss (and therefore momentum defect) at a point where the static pressure has reached the free-stream value. Thus on a non-lifting airfoil,

\[
D_o = \rho \int \int \sqrt{U_2(U_o - U_2)} dS
\]

and (on the foregoing assumption)

\[
H_o - p_0 = \frac{1}{2} \rho U_2^2
\]

Then

\[
D_o = \frac{2}{c} \int \int \sqrt{H_o - p_2} (\sqrt{H_2 - p_2} + \sqrt{H_2 - p_2}) dS
\]

Reduced to coefficient form, equation (9) becomes

\[
c_{d_0} = \frac{2}{c} \int \int \sqrt{H_2 - p_2} \left( 1 - \frac{1}{\sqrt{H_o - p_2}} \right) dS
\]
In addition to the foregoing errors, inaccuracies will possibly arise from incorrect readings of static and total pressures caused by turbulence and stream angularities behind the airfoil.

RESULTS AND DISCUSSION

COMPUTATION OF RESULTS

In the computation of results, the values of $H_z$ and $p_z$ across the wake profile were determined from faired curves of total and static pressures, to which a correction was applied to allow for the vertical gradients existing in the tunnel. The values of $H_0$ and $p_0$ were determined from readings taken well outside the wake with a correction applied to obtain the values of these quantities at the position of the airfoil. These values were then substituted in equations (4) and (10) and the results were plotted against the vertical position in the wake. The resulting curve was integrated, the summation being the section profile-drag coefficient at the station of measurement. An additional correction was applied for displacement of the effective center of the total-pressure tubes in a velocity gradient.

EFFECT OF DISTANCE BEHIND THE AIRFOIL

The variation in measured drag with distance behind the airfoil is shown in figure 5 for the three airfoils at a $c_l$ of 0.05 and for the N. A. C. A. 0012 at values of $c_l$ of 0.78 and 1.32. Each point is the average of results from two or more surveys. The curves show that the greatest difference in drag, as measured at the foremost and the rearmost positions, is approximately 3 percent. This difference is within the experimental scatter of the measurements, estimated to vary from ±1 percent at the 0.15$c$ station to ±3 percent at the 3.00$c$ station (where the wake profiles are shallow and wide). It is therefore concluded that the measured drag, as evaluated by either the Jones or the Betz method, is unaffected by distance behind the airfoil within the accuracy of the measurements.

Figure 5 also indicates that there is no significant difference between the drag as determined by the Betz and the Jones equations. The maximum spread between the two methods is less than 1 percent. All further drag determinations were therefore made by the Jones equation because of the greater simplicity of the necessary computations.

The results of other similar investigations (references 2, 7, and 8) are shown in figure 6. From these results, Muttray concluded (reference 7) that sufficient data had not yet been obtained to warrant the conclusion that the measured drag was independent of the distance behind the airfoil. The present investigation is considered, however, to have furnished sufficient data to support this conclusion.

EFFECT OF TURBULENCE ON STATIC-PRESSURE MEASUREMENTS

In relation to the possible effect of turbulence on the measurement of static pressure in the wake, a comparison of measured static pressures with computed static pressures behind the N. A. C. A. 0012 and 0018 airfoils at zero lift is shown in figure 7. The pressures behind the airfoils at zero lift were computed for the case of ideal flow about the airfoils and for flow with a boundary layer and a wake by means of a source-sink distribution to represent the airfoil and the wake.

COMPARISON OF MOMENTUM- AND FORCE-TEST RESULTS

The accuracy of the momentum method is indicated from a direct comparison with force-test results. The drag coefficients obtained from momentum surveys at 27 spanwise locations at 0.15$c$ behind the three airfoils at zero lift are plotted in figure 8. These curves, when integrated across the span, give an over-all $C_{D_0}$ for each airfoil. The drag coefficients obtained in this

manner are compared with those measured by force tests in table I. The maximum difference is less than 2 percent, indicating the order of accuracy of the momentum method. A similar comparison cannot be made at positive lifts because it is impossible to obtain results from the momentum method in the region of the airfoil tips owing to the intensity of the vortices.

EFFECT OF INDUCED FLOW

The total effect of the errors caused by the induced-flow field of a lifting airfoil may be determined from a comparison of the curves of section profile-drag coeffi-
cient against section lift coefficient obtained under the various conditions of induced flow that exist between the center line and the tip of a finite airfoil at positive lifts. Such curves are given in figure 9 for six spanwise locations from 0.06 to 0.90 \( b/2 \). The section lift coefficients were computed on the basis of a lift distribution given by Glaucert (reference 9), which was found to check well with pressure-distribution tests. These curves, having been slightly shifted in order to make them agree at zero lift, are superimposed in figure 10. It will be noted that, out to 0.78 \( b/2 \) and up to a \( c_e \) of 1.0, the maximum dispersion is ±2.5 percent from the 0.06 \( b/2 \) curve. This variation compares with a difference of approximately 7 percent that is indicated by Jones' analysis, which is based on the assumption of complete damping out of the vortices (reference 2). Inasmuch as part of the dispersion in figure 10 is due to experimental scatter, the ±2.5 percent is considered a conservative estimate of the effect of the induced field upon the measurements. At the 0.90 \( b/2 \) station, the distorted curve indicates that, above a section lift coefficient of zero, the air-stream angularities become such as to make the measurements unreliable.

COMPARISON OF MOMENTUM- AND FORCE-TEST RESULTS AT POSITIVE LIFTS

A direct comparison between drag results obtained from momentum and force tests of a lifting airfoil is impossible because of the failure of the momentum method near the tip as well as the inclusion of induced drag in the force-test measurements. If the induced drag is deducted from the force-test drag, however, the two methods should give results differing only by the drag contributed by the tips. Such a comparison has been made in figures 11 and 12. A plot of profile drag (determined by the momentum method) against span-wise position is given in figure 11; the curves were extrapolated in the tip region and no allowance was made for an increase in drag at the tips. Integration of these curves across the span gives the average profile-drag coefficient \( C_{D_0} \), which has been plotted against \( C_L \) in figure 12. The result is compared with the profile-drag coefficient determined from force tests in the usual manner (i.e., by deducting the computed induced drag). A curve of section characteristics obtained by the momentum method (0.06 \( b/2 \) curve from fig.10) is also given to show the comparison with the average profile drag across the span.

An appreciable spread will be noted between the momentum- and the force-test results; the difference varies from 1 percent at zero lift to 22 percent at a \( C_L \) of 1.0. A number of causes other than tip effects

may contribute to this difference, including possible errors in the momentum method and uncertainties in computed induced drag and in the several corrections applied to the force-test results.

CONCLUSIONS

The results presented herein lead to the following conclusions with regard to the determination of profile drag by the momentum method and the application of the Betz and the Jones equations under the conditions of the present investigation:

1. The drag determined by the momentum method did not vary appreciably with distance behind the airfoil between stations ranging from 0.05c to 3.00c behind the trailing edge.

2. At zero lift, the drag determined by the momentum method agreed with that measured by force tests within 2 percent.

3. Inboard of 78 percent of the semispan, the effects of the induced-flow system of a lifting wing did not cause errors exceeding 2.5 percent at a $c_t$ of 1.0.

4. The Betz and the Jones equations gave results that agree within 0.5 percent at stations ranging from 0.05c to 3.00c back of the trailing edge.

5. For measurements made no farther than 3.00c behind the trailing edge, the experimental scatter varied from 1 percent at zero lift to 3 percent at a $c_t$ of 1.0.
